2020 ACC/AHA Guideline for the Management of Patients With Valvular Heart Disease

A Report of the American College of Cardiology/American Heart Association Joint Committee on Clinical Practice Guidelines

WRITING COMMITTEE MEMBERS*

Catherine M. Otto, MD, FACC, FAHA, Co-Chair
Rick A. Nishimura, MD, MACC, FAHA, Co-Chair
Robert O. Bonow, MD, MS, MACC, FAHA
Blase A. Carabello, MD, FACC, FAHA
John P. Erwin III, MD, FACC, FAHA
Federico Gentile, MD, FACC
Hani Jneid, MD, FACC, FAHA
Eric V. Krieger, MD, FACC
Michael Mack, MD, MACC
Christopher McLeod, MBCHB, PhD, FAHA
Patrick T. O’Gara, MD, MACC, FAHA†
Vera H. Rigolin, MD, FACC, FAHA
Thoralf M. Sundt III, MD, FACC, FAHA
Annemarie Thompson, MD
Christopher Toly

*Writing committee members are required to recuse themselves from voting on sections to which their specific relationships with industry may apply; see Appendix 1 for detailed information.

Key Words: AHA Scientific Statements
- anticoagulation therapy
- aortic regurgitation
- aortic stenosis
- bicuspid aortic valve
- cardiac surgery
- guidelines
- infective endocarditis
- mitral regurgitation
- mitral stenosis
- mitral transcatheter edge-to-edge repair
- prosthetic valve
- pulmonic regurgitation
- pulmonic stenosis
- transcatheter aortic valve replacement or implantation
- tricuspid regurgitation
- tricuspid stenosis
- valvular heart disease

February 2, 2021 e73
TOP 10 TAKE-HOME MESSAGES

1. Disease stages in patients with valvular heart disease should be classified (Stages A, B, C, and D) on the basis of symptoms, valve anatomy, the severity of valve dysfunction, and the response of the ventricle and pulmonary circulation.

2. In the evaluation of a patient with valvular heart disease, history and physical examination findings should be correlated with the results of noninvasive testing (ie, ECG, chest x-ray, transthoracic echocardiogram). If there is discordance between the physical examination and initial noninvasive testing, consider further noninvasive (computed tomography, cardiac magnetic resonance imaging, stress testing) or invasive (transesophageal echocardiography, cardiac catheterization) testing to determine optimal treatment strategy.

3. For patients with valvular heart disease and atrial fibrillation (except for patients with rheumatic mitral stenosis or a mechanical prosthesis), the decision to use oral anticoagulation to prevent thromboembolic events, with either a vitamin K antagonist or a non–vitamin K antagonist anticoagulant, should be made in a shared decision-making process based on the CHA2DS2-VASc score. Patients with rheumatic mitral stenosis or a mechanical prosthesis and atrial fibrillation should receive oral anticoagulation with a vitamin K antagonist.

4. All patients with severe valvular heart disease being considered for valve intervention should be evaluated by a multidisciplinary team, with either referral to or consultation with a Primary or Comprehensive Valve Center.

5. Treatment of severe aortic stenosis with either a transcatheter or surgical valve prosthesis should be based primarily on symptoms or reduced ventricular systolic function. Earlier intervention may be considered if indicated by results of exercise testing, biomarkers, rapid progression, or the presence of very severe stenosis.

6. Indications for transcatheter aortic valve implantation are expanding as a result of multiple randomized trials of transcatheter aortic valve implantation versus surgical aortic valve replacement. The choice of type of intervention for a patient with severe aortic stenosis should be a shared decision-making process that considers the lifetime risks and benefits associated with type of valve (mechanical versus bioprosthetic) and type of approach (transcatheter versus surgical).

7. Indications for intervention for valvular regurgitation are relief of symptoms and prevention of the irreversible long-term consequences of left ventricular volume overload. Thresholds for intervention now are lower than they were previously because of more durable treatment options and lower procedural risks.

8. A mitral transcatheter edge-to-edge repair is of benefit to patients with severely symptomatic primary mitral regurgitation who are at high or prohibitive risk for surgery, as well as to a select subset of patients with secondary mitral regurgitation who remain severely symptomatic despite guideline-directed management and therapy for heart failure.

9. Patients presenting with severe symptomatic isolated tricuspid regurgitation, commonly associated with device leads and atrial fibrillation, may benefit from surgical intervention to reduce symptoms and recurrent hospitalizations if done before...
the onset of severe right ventricular dysfunction or end-organ damage to the liver and kidney.

10. Bioprosthetic valve dysfunction may occur because of either degeneration of the valve leaflets or valve thrombosis. Catheter-based treatment for prosthetic valve dysfunction is reasonable in selected patients for bioprosthetic leaflet degeneration or paravalvular leak in the absence of active infection.

PREAMBLE

Since 1980, the American College of Cardiology (ACC) and American Heart Association (AHA) have translated scientific evidence into clinical practice guidelines with recommendations to improve cardiovascular health. These guidelines, which are based on systematic methods to evaluate and classify evidence, provide a foundation for the delivery of quality cardiovascular care. The ACC and AHA sponsor the development and publication of clinical practice guidelines without commercial support, and members volunteer their time to the writing and review efforts. Guidelines are official policy of the ACC and AHA. For some guidelines, the ACC and AHA partner with other organizations.

Intended Use

Clinical practice guidelines provide recommendations applicable to patients with or at risk of developing cardiovascular disease. The focus is on medical practice in the United States, but these guidelines are relevant to patients throughout the world. Although guidelines may be used to inform regulatory or payer decisions, the intent is to improve quality of care and align with patients’ interests. Guidelines are intended to define practices meeting the needs of patients in most, but not all, circumstances, and should not replace clinical judgment.

Clinical Implementation

Management, in accordance with guideline recommendations, is effective only when followed by both practitioners and patients. Adherence to recommendations can be enhanced by shared decision-making between clinicians and patients, with patient engagement in selecting interventions on the basis of individual values, preferences, and associated conditions and comorbidities.

Methodology and Modernization

The ACC/AHA Joint Committee on Clinical Practice Guidelines (Joint Committee) continuously reviews, updates, and modifies guideline methodology on the basis of published standards from organizations, including the Institute of Medicine,1,2 and on the basis of internal reevaluation. Similarly, presentation and delivery of guidelines are reevaluated and modified in response to evolving technologies and other factors to optimally facilitate dissemination of information to healthcare professionals at the point of care.

Numerous modifications to the guidelines have been implemented to make them shorter and enhance “user-friendliness.” Guidelines are written and presented in a modular “knowledge chunk” format, in which each chunk includes a table of recommendations, a brief synopsis, recommendation-specific supportive text and, when appropriate, flow diagrams or additional tables. Hyperlinked references are provided for each modular knowledge chunk to facilitate quick access and review. Word limit targets and a web supplement for useful but noncritical tables and figures are 2 recent modifications.

In recognition of the importance of cost–value considerations, in certain guidelines, when appropriate and feasible, an analysis of value for a drug, device, or intervention may be performed in accordance with the ACC/AHA methodology.3

To ensure that guideline recommendations remain current, new data will be reviewed on an ongoing basis by the writing committee and staff. Going forward, targeted sections or knowledge chunks will be revised dynamically after publication and timely peer review of potentially practice-changing science. The previous designations of “full revision” and “focused update” will be phased out. For additional information and policies on guideline development, readers may consult the ACC/AHA guideline methodology manual4 and other methodology articles.5–7

Selection of Writing Committee Members

The Joint Committee strives to ensure that the guideline writing committee members have requisite content expertise and are representative of the broader cardiovascular community. Experts are selected across a spectrum of backgrounds, representing different geographic regions, sexes, races, ethnicities, intellectual perspectives or biases, and clinical practice settings. Organizations and professional societies with related interests and expertise are invited to participate as partners or collaborators.

Relationships With Industry and Other Entities

The ACC and AHA have rigorous policies and methods to ensure that documents are developed without bias or improper influence. The complete policy on relationships with industry and other entities (RWI) can be found at https://www.acc.org/guidelines/about-guidelines-and-clinical-documents/relationships-with-industry-policy. Appendix 1 of the guideline lists writing committee members’ relevant RWI; for the purposes of
full transparency, their comprehensive disclosure information is available online (https://www.ahajournals.org/doi/suppl/10.1161/CIR.0000000000000923). Comprehensive disclosure information for the Joint Committee is also available at https://www.acc.org/guidelines/about-guidelines-and-clinical-documents/guidelines-and-documents-task-forces.

Evidence Review and Evidence Review Committees

In developing recommendations, the writing committee uses evidence-based methodologies that are based on all available data. Literature searches focus on randomized controlled trials (RCTs) but also include registries, nonrandomized comparative and descriptive studies, case series, cohort studies, systematic reviews, and expert opinion. Only key references are cited.

An independent evidence review committee is commissioned when there are one or more questions deemed of utmost clinical importance that merit formal systematic review to determine which patients are most likely to benefit from a drug, device, or treatment strategy, and to what degree. Criteria for commissioning an evidence review committee and formal systematic review include absence of a current authoritative systematic review, feasibility of defining the benefit and risk in a time frame consistent with the writing of a guideline, relevance to a substantial number of patients, and likelihood that the findings can be translated into actionable recommendations. Evidence review committee members may include methodologists, epidemiologists, clinicians, and bio-statisticians. Recommendations developed by the writing committee on the basis of the systematic review are marked “SR.”

Guideline-Directed Management and Therapy

The term guideline-directed management and therapy (GDMT) encompasses clinical evaluation, diagnostic testing, and both pharmacological and procedural treatments. For these and all recommended drug treatment regimens, the reader should confirm dosage with product insert material and evaluate for contraindications and interactions. Recommendations are limited to drugs, devices, and treatments approved for clinical use in the United States.

Patrick T. O’Gara, MD, MACC, FAHA
Chair, ACC/AHA Joint Committee on Clinical Practice Guidelines

1. INTRODUCTION

1.1. Methodology and Evidence Review

The recommendations listed in this document are, whenever possible, evidence based. An extensive review was conducted on literature published through March 1, 2020. Searches were extended to studies, reviews, and other evidence involving human subjects that were published in English and indexed in PubMed, EMBASE, Cochrane, Agency for Healthcare Research and Quality Reports, and other selected databases relevant to this guideline. Key search words included but were not limited to the following: valvular heart disease, aortic stenosis, aortic regurgitation, bicuspid aortic valve, mitral stenosis, mitral regurgitation, tricuspid stenosis, tricuspid regurgitation, pulmonic stenosis, pulmonic regurgitation, prosthetic valves, anticoagulation therapy, infective endocarditis, cardiac surgery, transcatheter aortic valve replacement or implantation, and percutaneous mitral clip. Additionally, the committee reviewed documents related to the subject matter previously published by the ACC and AHA. The references selected and published in this document are representative and not all-inclusive.

1.2. Organization of the Writing Committee

The writing committee was composed of clinicians, which included cardiologists, interventionalists, surgeons, anesthesiologists, and a patient representative. Members were required to disclose all RWI relevant to the data under consideration.

1.3. Document Review and Approval

This document was reviewed by 2 official reviewers each nominated by the ACC and the AHA, as well as content reviewers nominated by the ACC and AHA. Reviewers’ RWI information was distributed to the writing committee and is published in this document (Appendix 2).

1.4. Scope of the Guideline

The focus of this guideline is the diagnosis and management of adult patients with valvular heart disease (VHD). A full revision of the original 1998 VHD guideline was made in 2006, and an update was made in 2008. Another full revision was made in 2014, with an update in 2017. There was an additional statement of clarification specifically for surgery for aortic dilation in patients with bicuspid aortic valves (BAV) in 2016. The present guideline will replace the 2014 guideline and 2017 focused update. Some recommendations from the earlier VHD guidelines have been updated as warranted by new evidence or a better understanding of
earlier evidence, whereas others that were inaccurate, irrelevant, or overlapping were deleted or modified. Throughout, our goal was to provide the clinician with concise, evidence-based, contemporary recommendations and the supporting documentation to encourage their use. Where applicable, sections were divided into subsections of 1) diagnosis and follow-up, 2) medical therapy, and 3) intervention. The purpose of these subsections is to categorize the Class of Recommendation according to the clinical decision-making pathways that caregivers use in the management of patients with VHD.

The document recommends a combination of lifestyle modifications and medications that constitute components of GDMT. For both GDMT and other recommended drug treatment regimens, the reader is advised to confirm dosages with product insert material and to carefully evaluate for contraindications and drug–drug interactions. Table 1 is a list of associated guidelines that may be of interest to the reader.

### 1.5. Class of Recommendation and Level of Evidence

The Class of Recommendation (COR) indicates the strength of recommendation, encompassing the estimated magnitude and certainty of benefit in proportion to risk. The Level of Evidence (LOE) rates the quality of scientific evidence supporting the intervention on the basis of the type, quantity, and consistency of data from clinical trials and other sources (Table 2).1

2. GENERAL PRINCIPLES

2.1. Evaluation of the Patient With Known or Suspected Native VHD

Patients with VHD may present with a heart murmur, symptoms, or incidental findings of valvular abnormalities on noninvasive testing. Irrespective of the presentation, all patients with known or suspected VHD should undergo an initial meticulous history and physical examination. A detailed physical examination should be performed to diagnose and assess the severity of valve lesions. An electrocardiogram (ECG) to confirm heart rhythm and a chest x-ray to assess the presence or absence of pulmonary congestion or other lung pathology may be helpful in the initial assessment of patients with known or suspected VHD. A comprehensive transthoracic echocardiogram (TTE) with 2-dimensional (2D) imaging and Doppler interrogation should be performed for diagnosis and evaluation of known or suspected VHD. The TTE also provides additional information, such as transesophageal echocardiography (TEE), computed tomography (CT), cardiac magnetic resonance (CMR) imaging, stress testing, Holter monitoring, diagnostic hemodynamic cardiac catheterization, or positron emission tomography (PET) combined with CT imaging. If intervention is contemplated, surgical or procedural risk should be estimated and other factors also considered, including comorbidities, frailty, and patient preferences and values (Table 3).

2.2. Definitions of Severity of Valve Disease

Classification of valve disease severity is based on multiple criteria, including symptoms, valve anatomy, valve hemodynamics and the effects of valve dysfunction on ventricular and vascular function (eg, end-organ damage). Surgical and transcatheter interventions are performed primarily on patients with severe VHD, but diagnosis, patient education, periodic monitoring, and medical therapy are essential elements in the management of patients at risk of VHD and with mild to moderate valve dysfunction. This document provides a classification of the progression of VHD, with 4 stages (A to D). Indications for intervention and periodic monitoring are dependent on 1) the presence or absence of symptoms, 2) the severity of VHD, 3) the response of the LV and/or RV to volume or pressure overload caused by VHD, and 4) the effects on the pulmonary or systemic circulation (Table 4). The purpose of valvular intervention is to improve symptoms, prolong survival, and minimize the risk of VHD-related complications, such as irreversible ventricular dysfunction, pulmonary hypertension, stroke, and atrial fibrillation (AF). Thus, the criteria for “severe” VHD are based on predictors of clinical outcome from observational studies, registry data, and randomized clinical trials (RCTs) of patients with VHD. Of course, severity is a continuous variable; categorizing disease into stages, from A to D, simply provides a framework, or starting point, for diagnosis and management, and it is recognized that not all patients will fit perfectly into a specific stage. Some patients will have symptoms or end-organ damage with valve hemodynamics that do not quite meet specific disease severity criteria, and numerical measures may not match exactly across all categories. Conversely, other patients may remain asymptomatic without obvious evidence of end-organ damage despite apparently severe VHD. Criteria for the stages of each individual valve lesion are listed in Section 3.1 (Table 13), Section 4.2 (Table 15), Section 6.1 (Table 16), Section 7.2 (Table 17), Section 7.3 (Table 18), and Section 8.1 (Table 20).

2.3. Diagnosis and Follow-Up

2.3.1. Diagnostic Testing: Initial Diagnosis

TTE is the standard diagnostic test in the initial evaluation of patients with known or suspected VHD.1-4
TTE allows accurate assessment of valve anatomy and etiology, concurrent valve disease, and associated abnormalities, such as aortic dilation. Left ventricular (LV) anatomy and function are characterized by linear dimensions, as well as by 2D and 3D volumes and ejection fraction (LVEF), and it is recognized that decisions are most robust when based on sequential studies, given the inherent measurement variability for these parameters.\(^5\) Doppler echocardiography provides accurate noninvasive determination of valve hemodynamics.\(^1,2,6\)

For stenotic lesions, key measurements are maximum velocity, mean gradient, and valve area. For regurgitant lesions, calculation of regurgitant orifice area, volume, and fraction is performed, when possible in the context of a multiparameter severity grade based on color Doppler imaging, continuous- and pulsed-wave Doppler recordings, and the presence or absence of distal flow reversals. Pulmonary systolic pressure also is estimated, along with qualitative evaluation of right ventricular (RV) size and function.\(^7\)

COT and LOE are determined independently (any COT may be paired with any LOE).

A recommendation with LOE C does not imply that the recommendation is weak. Many important clinical questions addressed in guidelines do not lend themselves to clinical trials. Although RCTs are unavailable, there may be a very clear clinical consensus that a particular test or therapy is useful or effective.

* The outcome or result of the intervention should be specified (an improved clinical outcome or increased diagnostic accuracy or incremental prognostic information).

† For comparative-effectiveness recommendations (COT 1 and 2a; LOE A and B only), studies that support the use of comparator verbs should involve direct comparisons of the treatments or strategies being evaluated.

‡ The method of assessing quality is evolving, including the application of standardized, widely-used, and preferably validated evidence grading tools; and for systematic reviews, the incorporation of an Evidence Review Committee.

COR indicates Class of Recommendation; E0, expert opinion; LD, limited data; LOE, Level of Evidence; NR, nonrandomized; R, randomized; and RCT, randomized controlled trial.

Circulation. 2021;143:e72–e227. DOI: 10.1161/CIR.0000000000000923

February 2, 2021 e79
2.3.2. Diagnostic Testing: Changing Signs or Symptoms

Patients with VHD should be instructed to promptly report any change in symptom status. The onset of symptoms or a change in the physical examination should raise concern about the cardiac response to the valve lesion, necessitating a repeat TTE. A repeat comprehensive TTE study can determine whether symptoms are caused by progressive valve dysfunction, deterioration of the ventricular response to the volume or pressure overload, or another etiology. New signs on physical examination also warrant a repeat TTE.

2.3.3. Diagnostic Testing: Routine Follow-Up

After initial evaluation of an asymptomatic patient with VHD, the clinician should continue regular follow-up with periodic examinations and TTE. The purpose of follow-up is to prevent the irreversible consequences of severe VHD, primarily affecting the status of the ventricles and pulmonary circulation, which may occur in the absence of symptoms. At a minimum, a yearly history and physical examination are necessary. The frequency of repeat 2D and Doppler echocardiography is based on the type and severity of the valve lesion, the known rate of progression of the specific valve lesion, and the effect of the valve lesion on the affected ventricle (Table 5).

 Patients with Stages C2 and D disease are not included in this table because they would be considered candidates for intervention. The follow-up interval may be extended in patients with mild regurgitation who show no change over a 10- to 15-year period. In addition to routine periodic imaging, the onset of symptoms or a change in the physical examination should raise concern about the cardiac response to the valve lesion, necessitating a repeat TTE.

2.3.4. Diagnostic Testing: Cardiac Catheterization

Although TTE is now able to provide the required anatomic and hemodynamic information in most cases of VHD, cardiac catheterization may be indicated in some situations, particularly when preoperative assessment is required. The decision to perform cardiac catheterization should be made in consultation with a cardiovascular specialist.
patients with VHD, there is still a subset of patients in whom hemodynamic catheterization is necessary to ensure that the proper decision about treatment is made. If noninvasive testing yields inconclusive data, particularly in the symptomatic patient, or if there is a discrepancy between the noninvasive tests and clinical findings, a hemodynamic cardiac catheterization with direct intracardiac measurements of transvalvular pressure gradients and cardiac output measurements provides valuable clinical information. Severity of stenosis may be underestimated when imaging is difficult or when the Doppler beam is not aligned parallel to the direction of the high-velocity jet. Severity of valve regurgitation may be overstated or underestimated if the image or Doppler data quality is suboptimal. Contrast angiography is sometimes useful for a semiquantitative assessment of the severity of regurgitation in those instances in which the noninvasive results are discordant with the physical examination. A major advantage of cardiac catheterization is the measurement of intracardiac pressures and pulmonary vascular resistance, which may further aid in decision-making about valve intervention. Diagnostic interventions that can be performed in the catheterization laboratory include the use of dobutamine in low-flow states, pulmonary vasodilators in pulmonary hypertension, and exercise hemodynamics in patients with discrepant symptoms. A hemodynamic catheterization needs to be done with meticulous attention to detail by persons with knowledge and expertise in assessing patients with VHD.

### 2.3.5. Diagnostic Testing: Exercise Testing

In a subset of patients, exercise stress testing will be of additional value in determining optimal therapy. Because of the slow, insidious rate of progression of many valve lesions, patients may deny symptoms as they gradually limit their activity level over several years to match the gradual limitations imposed by the valve lesion. In patients with an equivocal history of symptoms, exercise testing helps identify those who are truly symptomatic. Exercise stress testing (ie, examining the exercise capacity and blood pressure response) is of prognostic value in patients with asymptomatic valve disease and provides further information about the timing of a potential intervention. It is important that exercise testing in patients with severe VHD always be performed by trained operators, with continuous monitoring of the ECG and blood pressure.

### 2.4. Basic Principles of Medical Therapy

In patients being evaluated for VHD, standard GDMT for cardiac risk factors, including hypertension, diabetes mellitus, and hyperlipidemia, should not be neglected. Heart-healthy lifestyle factors (exercising, consuming a healthy diet, not smoking, and maintaining a normal body size) are no different for patients with VHD than for the general population. Many patients with asymptomatic VHD feel better with regular aerobic exercise to improve cardiovascular fitness. Although heavy isometric repetitive training might increase LV afterload, resistive training with small free weights or repetitive

*With normal stroke volume.
LV indicates left ventricle; MV, mitral valve; VHD, valvular heart disease; and V<sub>max</sub>, maximum velocity.

Patients with mixed valve disease may require serial evaluations at intervals earlier than recommended for single-valve lesions. These intervals apply to most patients with each valve lesion and do not take into consideration the etiology of the valve disease.
isolated muscle training may be used to strengthen individual muscle groups. Most patients with LV systolic dysfunction and severe VHD will undergo intervention for the valve itself. However, if intervention is declined or not feasible, standard GDMT drug therapy for LV systolic dysfunction should be continued, including diuretics, angiotensin-converting enzyme (ACE) inhibitors, aldosterone antagonists, and/or sacubitril/valsartan and biventricular pacing, as indicated in the guidelines for heart failure (HF). In patients with stenotic valve lesions, abrupt lowering of blood pressure should be avoided. Rheumatic fever prophylaxis and infective endocarditis (IE) prophylaxis should be provided to appropriate groups of patients, as outlined in Sections 2.4.1 and 2.4.2. The maintenance of optimal oral health remains the most important component of an overall healthcare program in preventing IE. Influenza and pneumococcal vaccinations should follow standard recommendations in patients with VHD. For subsets of patients with AF and VHD, anticoagulation is discussed in Section 2.4.3.

*Lifelong prophylaxis may be recommended if the patient is at high risk of group A streptococcus exposure. Secondary rheumatic heart disease prophylaxis is required even after valve replacement.†Clinical or echocardiographic evidence. VHD indicates valvular heart disease. Adapted from Gerber et al.

### 2.4.2. IE Prophylaxis

**Recommendation-Specific Supportive Text**

1. Recurrent rheumatic fever is associated with a worsening of rheumatic heart disease. However, infection with group A streptococcus does not have to be symptomatic to trigger a recurrence, and rheumatic fever can recur even when the symptomatic infection is treated. Prevention of recurrent rheumatic fever requires long-term antimicrobial prophylaxis rather than recognition and treatment of acute episodes of group A streptococcus pharyngitis. The recommended treatment regimen and duration of secondary prophylaxis are shown in Tables 6 and 7.

#### 2.4.2. IE Prophylaxis

**Recommendations for IE Prophylaxis**

### Synopsis

Rheumatic fever is an important cause of VHD worldwide, although it is less common in high-income countries. Rapid detection and treatment of streptococcal pharyngitis constitute primary prevention of rheumatic fever. For patients with previous episodes of rheumatic fever or in those with evidence of rheumatic heart disease, long-term antistreptococcal prophylaxis is indicated for secondary prevention.
Synopsis
With the absence of RCTs addressing the efficacy of antibiotic prophylaxis for prevention of IE\textsuperscript{1,12–14} and given uncertainty about which patient populations are at highest risk, these recommendations are based on pathophysiological considerations, limited data, and clinical expertise. A prospective study demonstrated that prophylactic antibiotics given to patients for what is typically considered a high-risk dental procedure reduced but did not eliminate the incidence of bacteremia.\textsuperscript{2} A 2013 Cochrane Database systematic review of antibiotic prophylaxis for the prevention of IE in dentistry concluded that there is no evidence to determine whether antibiotic prophylaxis is effective or ineffective, highlighting the need for further study of this long-standing clinical dilemma.\textsuperscript{1} Epidemiological data conflict with regard to changes in the incidence of IE after adoption of more limited antibiotic prophylaxis guidelines.\textsuperscript{15–22} The consensus of the writing committee is that antibiotic prophylaxis is reasonable for the subset of patients at highest risk of developing IE and at high risk of experiencing adverse outcomes from IE. There is no evidence for IE prophylaxis in gastrointestinal procedures or genitourinary procedures, in the absence of known active infection.

Recommendation-Specific Supportive Text
1. The risk of developing IE is highest in patients with a prosthetic valve, prior IE, or congenital heart disease with residual flow disturbances.\textsuperscript{3} IE has been reported to occur after transcatheter aortic valve implantation (TAVI) at rates equal to or exceeding those associated with surgical aortic valve replacement (SAVR) and is associated with a high 1-year mortality rate of 75%.\textsuperscript{23,24} IE may also occur after valve repair with prosthetic material, which results in high in-hospital and 1-year mortality rates, even with surgical intervention.\textsuperscript{25,26} IE appears to be more common in heart transplant recipients than in the general population, according to limited data.\textsuperscript{3} The risk of IE is highest in the first 6 months after transplantation because of endothelial disruption, high-intensity immunosuppressive therapy, frequent central venous catheter access, and frequent endomyocardial biopsies.\textsuperscript{3} Persons at risk of IE can reduce potential sources of bacterial seeding by maintaining optimal oral health through regular professional dental care and the use of appropriate dental products, such as manual, powered, and ultrasonic toothbrushes; dental floss; and other plaque-removal devices.

2. Transient bacteremia is commonly seen in routine activities such as brushing teeth and flossing (20% to 68%), using toothpicks (20% to 40%), and simply chewing food (7% to 51%).

2.4.3. Anticoagulation for AF in Patients With VHD

The incidence of IE after most procedures is low, with no controlled data supporting the benefit of antibiotic prophylaxis. Indiscriminate use of antibiotics can be associated with the development of resistant organisms, \textit{Clostridium difficile} colitis, unnecessary expense, and drug toxicity. The rate of transient bacteremia during or immediately after endoscopy is 2% to 5%, and the organisms typically identified are unlikely to cause IE.\textsuperscript{11,27,28} The rate of bacteremia does not increase with biopsy, polypectomy, or sphincterotomy. Some gastrointestinal procedures are associated with rates of bacteremia higher than that for simple endoscopy; these procedures include esophageal dilation (as high as 45%), sclerotherapy (31%), and endoscopic retrograde cholangiopancreatography (6% to 18%).\textsuperscript{29} However, no studies have shown reduced rates of IE with antibiotic prophylaxis. Surgery, instrumentation, or diagnostic procedures that involve the genitourinary tract may cause bacteremia. In the absence of infection, the rate of bacteremia after urinary tract procedures is low. In patients with bacteruria, antimicrobial therapy before elective procedures, including lithotripsy, typically is provided.\textsuperscript{30}

Synopsis
Patients with VHD and AF should be evaluated for risk of thromboembolic events and to treat them with oral anticoagulation if they are at high risk. VKAs are the anticoagulation drugs of choice for patients with rheumatic MS and mechanical heart valves. NOACs are an alternative to VKAs in patients with AF and 1) with
bioprosthetic valves >3 months after implantation or, 2) with native VHD excluding rheumatic MS (Figure 1).

**Recommendation-Specific Supportive Text**

1. The 4 large RCTs comparing NOACs with warfarin included small numbers of patients with VHD, prior valve repair, and bioprosthetic valves (excluding moderate to severe rheumatic MS and mechanical heart valves). In addition to the subsequent meta-analyses,1,15–17 examinations of insurance claims data and large registries18 have consistently confirmed no signal for a differential effect between NOAC and VKA therapy.19,20 More consistently observed is a net clinical benefit, with fewer events in patients using NOACs than in patients on VKA therapy. Validation of the CHA2DS2-VASc risk schema in patients with VHD (excluding moderate to severe rheumatic MS and mechanical heart valves) has been performed in large registries,2 confirming the applicability of this score. Bioprosthetic valves do not appear to be independent predictors of thromboembolic events in patients with AF.19

2. The coexistence of AF and rheumatic MS is common and confers a substantial risk of thromboembolic events. These patients have been specifically excluded from NOAC trials, yet a single registry study and a US claims database analysis do suggest that NOACs may be potentially preferable.21,22 These findings need further validation, and currently the use of NOACs cannot be supported over VKA (target international normalized ratio [INR] of 2.5).

3. Postoperative AF after VHD intervention is associated with increased stroke and mortality rates irrespective of the CHA2DS2-VASc score. Anticoagulation in this setting may reduce these endpoints. There are conflicting data about the safety and efficacy of NOAC therapy in patients early after implantation of a bioprosthesis.5,6,23 Until more data are available, the writing committee favors using VKA for patients with AF in the first 3 months after surgical or transcatheter bioprosthetic valve implantation to prevent thromboembolic events. The optimal duration of anticoagulation is not well defined. Repeat evaluation is encouraged in all patients to detect arrhythmia recurrence in the context of their CHA2DS2-VASc scores.

4. The phase II study comparing dabigatran to warfarin (RE-ALIGN [Randomized, Phase II Study to Evaluate the Safety and Pharmacokinetics of Oral Dabigatran Etxilate in Patients after Heart Valve Replacement]) was halted prematurely because of excess stroke and

*Use of the STS Predicted Risk of Mortality (http://riskcalc.sts.org/stswebriskcalc/#/) to predict risk in a given institution with reasonable reliability is appropriate only if institutional outcomes are within 1 standard deviation of the STS average observed/expected mortality ratio for the procedure in question. The EUROSCORE II risk calculator may also be considered for use and is available at http://www.euroscore.org/calc.html.
†Seven frailty indices: Katz Activities of Daily Living (independence in feeding, bathing, dressing, transferring, toileting, and urinary continence) plus independence in ambulation (no walking aid or assistance required, or completion of a 5-m walk in <6 s). Other scoring systems can be applied to calculate no, mild, or moderate to severe frailty.
‡Examples of major organ system compromise include cardiac dysfunction (severe LV systolic or diastolic dysfunction or RV dysfunction, fixed pulmonary hypertension); kidney dysfunction (chronic kidney disease, stage 3 or worse); pulmonary dysfunction (FEV1 <50% or DLCO2 <50% of predicted); central nervous system dysfunction (dementia, Alzheimer’s disease, Parkinson’s disease, cerebrovascular accident with persistent physical limitation); gastrointestinal dysfunction (Crohn’s disease, ulcerative colitis, nutritional impairment, or serum albumin <3.0); cancer (active malignancy); and liver dysfunction (any history of cirrhosis, variceal bleeding, or elevated INR in the absence of VKA therapy).
§Examples of procedure-specific impediments include presence of tracheostomy, heavily calcified (porcelain) ascending aorta, chest malformation, arterial coronary graft adherent to posterior chest wall, and radiation damage.

DLCO: diffusion capacity for carbon dioxide; FEV1: forced expiratory volume in 1 s; INR: international normalized ratio; LV: left ventricular; MR: mitral regurgitation; RV: right ventricular; SAVR: surgical aortic valve replacement; STS: Society of Thoracic Surgeons; and VKA: vitamin K antagonist.

bleeding in the dabigatran group. Until there is an explanation of why these adverse events occurred, there is insufficient evidence to support the use of NOACs for patients with mechanical heart valves.7

### Synopsis

Risk assessment has become a foundational element of the preprocedural evaluation of patients with VHD for whom intervention to correct the valve lesion may be contemplated. Although there are limitations to the scoring systems used to estimate the risk of adverse outcomes, these estimates provide a useful point of reference against which procedural benefits can be weighed. Numerical estimates of risk are just one component of the multidisciplinary team (MDT) assessment process, and factors not routinely included in risk algorithms (eg, liver disease, porcelain aorta) add important dimensions. The availability of TAVI for treatment of symptomatic severe aortic stenosis (AS) across the surgical risk spectrum emphasizes the need to have discussions about younger age at implantation, valve durability, and the potential need for permanent pacemaker implantation. For young patients (eg, <65 years of age) who opt for a surgical bioprosthesis, strategies for sequential procedures over a longer follow-up period (ie, valve-in-valve [ViV] TAVI versus reoperation) must be addressed.

### Recommendation-Specific Supportive Text

1. The decision to intervene, as well as the type of procedure recommended, is based on an assessment of patient-, procedure-, and institution- or operator-specific short-term risks and long-term benefits (Table 8). Surgical mortality rate and major morbidity risks can be calculated with a web-based tool derived from the Society of Thoracic Surgeons (STS) Adult Cardiac Surgery database for 6 specific procedures (http://riskcalc.sts.org/stswebriskcalc/calculate). TAVI-specific risk prediction tools are also available (http://tools.acc.org/TAVRRisk/#/content/evaluate/).1–6 Frailty assessment for at-risk patients is routine.7–11 Patients toward the higher end of the risk spectrum, for whom intervention would be futile or associated with a high likelihood of a poor outcome, should...

| 1      | C-EO | 1. Patients with severe VHD should be evaluated by a Multidisciplinary Heart Valve Team (MDT) when intervention is considered. |
| 2a     | C-LD | 2. Consultation with or referral to a Primary or Comprehensive Heart Valve Center is reasonable when treatment options are being discussed for 1) asymptomatic patients with severe VHD, 2) patients who may benefit from valve repair versus valve replacement, or 3) patients with multiple comorbidities for whom valve intervention is considered.12–15 |

Synopsis

The value of the MDT has become increasingly apparent as options in the treatment of VHD have broadened. Heart Valve Centers, in the context of an integrated multi-institutional model of care for patients with VHD, allow optimization of patient outcomes through improved decision-making and matching of patients to providers with appropriate expertise, experience, and resources.12 Primary and Comprehensive Heart Valve Centers are defined by their offerings and expertise in the management of patients with VHD12 (Table 11).

**Recommendation-Specific Supportive Text**

1. The MDT is an established feature of heart valve programs20 and has been formally endorsed by the ACC, the American Society of Echocardiography, the Society for Cardiovascular Angiography and Interventions, the American Association for Thoracic Surgery, and the STS.12 Key members of the MDT include cardiologists with subspecialty expertise in the clinical evaluation of patients with VHD, as well as specialists in advanced cardiovascular imaging. For the evaluation of the patient with secondary mitral regurgitation (MR) and tricuspid regurgitation (TR), a specialist in HF also is included. Interventional cardiologists with training and expertise in VHD and surgeons experienced in the treatment of VHD anchor the MDT. Other team members include cardiovascular nurses, cardiovascular anesthesiologists, and intensivists involved in periprocedural care. Finally, the engagement of the primary clinical cardiologist and patient is of critical importance. The MDT facilitates presentation of all appropriate options for medical, interventional, and surgical treatment to the patient in a balanced manner, using tools and techniques for shared decision-making in which patient preferences are considered.

2. Decision-making is particularly challenging for the asymptomatic VHD patient, for whom the risks of operative mortality and perioperative morbidity must be very low and the chances of a successful and durable surgical outcome very high. There is a substantial body of literature to support a relationship between institutional volume and mortality rate for many cardiovascular procedures, including SAVR,1–5 TAVI,6 and surgical mitral valve repair.7–11 Consideration should be given to consultation with or referral to a Primary or Comprehensive Heart Valve Center for asymptomatic patients with severe VHD. Although excellent outcomes certainly can be achieved at lower-volume centers, assurance of outcomes equivalent to those of a higher-volume center is statistically more challenging.12 Similarly, for patients with multiple comorbidities for whom multispecialty collaboration is anticipated, care at a Comprehensive or Primary Valve Center ensures optimal outcomes. Although findings are mixed,13 there are data to support relationships between center volume and complication rates in cardiac surgical care,14 between center volume and failure to rescue after procedural complications,15–17 and between center volume and elements of infrastructure support.18,19

2.7. Management of Patients With VHD After Valve Intervention

Interventions in patients with VHD include both transcatheter and surgical approaches. A valve intervention leaves the patient with either a prosthetic valve or a valve repair, often with an implanted device or other prosthetic material. Valve intervention does not eliminate valve disease; it replaces native valve disease with palliated valve disease. Patients with VHD continue to require periodic evaluation after intervention...
for early postprocedural issues, long-term medical therapy, monitoring of the prosthetic valve or repair, management of concurrent cardiac conditions, and persistent symptoms or functional limitation. Endocarditis prophylaxis is discussed in Section 2.4.2; antithrombotic therapy for prosthetic valves in Sections 11.2 to 11.5; and prosthetic valve complications, including valve thrombosis, stenosis, or regurgitation, in Sections 11.6 to 11.8.

2.7.1. Procedural Complications
The most common complication early after surgical valve replacement is postoperative AF, which occurs in up to one-third of patients within 3 months of surgery (see Sections 2.4.3 and 14.1). Other complications include stroke, vascular and bleeding complications, pericarditis, heart block requiring temporary or permanent pacing (especially after AVR), HF, renal dysfunction, and infection. Complications after transcatheter interventions depend on the specific procedure but can include the need for permanent pacing, paravalvular leak, stroke, vascular complications, and residual valve dysfunction.

2.7.2. Primary and Secondary Risk Factor Evaluation and Treatment
Concurrent coronary artery disease (CAD) is common in adults with VHD. Management of CAD at the time of valve intervention is discussed in Section 14.2. After valve intervention, evaluate and treat patients with CAD risk factors according to current guidelines for primary and secondary prevention. Although there is no convincing evidence that treating CAD risk factors will reduce the likelihood of progressive valve dysfunction after intervention, cardiovascular outcomes are improved overall because of a reduced rate of coronary events.

2.7.3. Persistent Symptoms After Valve Intervention
Persistent symptoms occur in many patients after valve intervention. The first step in evaluation is to assess valve function to ensure symptoms are not caused by persistent or recurrent stenosis, regurgitation, or a valve complication. The next step is to evaluate and treat any concurrent cardiac disease and noncardiac conditions that may be the cause of symptoms. Symptoms also may be attributable to irreversible consequences of valve disease, including LV systolic and diastolic dysfunction, pulmonary hypertension, and RV dysfunction. Treatment of symptoms for these patients is based on GDMT for HF and/or pulmonary hypertension.

2.7.4. Periodic Imaging After Valve Intervention

<td>1. In asymptomatic patients with any type of valve intervention, a baseline postprocedural TTE followed by periodic monitoring with TTE is recommended, depending on type of intervention, length of time after intervention, ventricular function, and concurrent cardiac conditions.</td>
</tr>
</tbody>
</table>

**Synopsis**
A TTE is useful after either catheter-based or surgical intervention to provide a baseline measurement of valve function and the status of the ventricle. Repeat TTE is recommended with either new symptoms or a change in the physical examination. The timing of periodic follow-up imaging is based on the type of valve intervention.

</tbody>
</table>

*Initial postprocedural TTE is recommended for all patients, ideally 1 to 3 months after the procedure. Annual clinical follow-up is recommended annually for all patients after valve intervention at a Primary or Comprehensive Valve Center.

†Repeat imaging is appropriate at shorter follow-up intervals for changing signs or symptoms, during pregnancy, and to monitor residual or concurrent cardiac dysfunction.

‡Imaging may be done more frequently in patients with bioprosthetic surgical valves if there are risk factors for early valve degeneration (eg, younger age, renal failure, diabetes).

AVR indicates aortic valve replacement; and TTE, transthoracic echocardiography.
3. AORTIC STENOSIS

3.1. Stages of Valvular AS

Medical and interventional approaches to the management of patients with valvular AS depend on accurate diagnosis of the cause and stage of the disease process. Table 13 shows the stages of AS, ranging from patients at risk of AS (Stage A) or with progressive hemodynamic obstruction (Stage B) to severe asymptomatic (Stage C) and symptomatic AS (Stage D). Each stage is defined by patient symptoms, valve anatomy, valve hemodynamics, and changes in the LV and vasculature. Hemodynamic severity is best characterized by the transaortic maximum velocity (or mean pressure gradient) when the transaortic volume flow rate is normal. Some patients with AS have a low transaortic volume flow rate that is either because of LV systolic dysfunction with a low LVEF or because of a small, hypertrophied LV with a low stroke volume. Severe AS with low flow is designated D2 (with a low LVEF) or D3 (with a normal LVEF). Meticulous attention to detail is required during assessment of aortic valve hemodynamics, either with Doppler echocardiography or cardiac catheterization, and the inherent variability of the measurements and calculations should always be considered in clinical decision-making.

3.2. Aortic Stenosis

3.2.1. Diagnosis and Follow-Up

3.2.1.1. Diagnostic Testing: Initial Diagnosis

| Recommendations for Diagnostic Testing: Initial Diagnosis of AS |
|-----------------|-----------------|-----------------|
| COR | LOE | Recommendations |
| 1 | A | 1. In patients with signs or symptoms of AS or a BAV, TTE is indicated for accurate diagnosis of the cause of AS, assessment of hemodynamic severity, measurement of LV size and systolic function, and determination of prognosis and timing of valve intervention. |
| 1 | B-NR | 2. In patients with suspected low-flow, low-gradient severe AS with normal LVEF (Stage D3), optimization of blood pressure control is recommended before measurement of AS severity by TTE, TEE, cardiac catheterization, or CMR. |
| 2a | B-NR | 3. In patients with suspected low-flow, low-gradient severe AS with reduced LVEF (Stage D2), low-dose dobutamine stress testing with echocardiographic or invasive hemodynamic measurements is reasonable to further define severity and assess contractile reserve. |
| 2a | B-NR | 4. In patients with suspected low-flow, low-gradient severe AS with normal or reduced LVEF (Stages D2 and D3), calculation of the ratio of the outflow tract to aortic velocity is reasonable to further define severity. |
| 2a | B-NR | 5. In patients with suspected low-flow, low-gradient severe AS with normal or reduced LVEF (Stages D2 and D3), measurement of aortic valve calcium score by CT imaging is reasonable to further define severity. |

Synopsis

The overall approach to the initial diagnosis of VHD is discussed in Section 2.3, and additional considerations specific to patients with AS are addressed here.

Recommendation-Specific Supportive Text

1. In adult patients, physical examination may not be accurate for diagnosis of and assessment of severity of AS. Echocardiographic imaging allows reliable evaluation of valve anatomy and motion and the degree of valve obstruction. In addition, TTE is useful for measuring LV size and systolic function, identifying concurrent AR or MR, and estimating pulmonary systolic pressure. 1,2,11,12,19–27

2. Measurements of AS severity made when the patient is hypertensive may underestimate or, less often, overestimate stenosis severity. Systemic hypertension imposes a second pressure load on the LV, in addition to valve obstruction, which

AR indicates aortic regurgitation; AS, aortic stenosis; AVA, aortic valve area circulation; AVAi, AVA indexed to body surface area; BAV, bicuspid aortic valve; \( \Delta P \), pressure gradient between the LV and aorta HF, heart failure; LV, left ventricular; LVEF, left ventricular ejection fraction; and \( V_{\text{max}} \), maximum velocity.

Results in a lower forward stroke volume and lower transaortic pressure gradient than when the patient is normotensive. Thus, Doppler velocity data and invasive pressure measurements ideally are recorded when the patient is normotensive. If results indicate only moderate stenosis but were recorded when the patient was hypertensive, repeat measurements when the blood pressure is better controlled ensure that a diagnosis of severe AS is not missed.

3. Patients with severe AS and LVEF <50% present with an aortic valve area <1.0 cm\(^2\) but a low transvalvular velocity and pressure gradient (ie, velocity <4 m/s or mean gradient <40 mmHg) at rest. In these patients, severe AS with LV systolic dysfunction attributable to afterload...

**CLINICAL STATEMENTS AND GUIDELINES**

*February 2, 2021 e91*
mismatch must be distinguished from primary myocardial dysfunction with only moderate AS. Dobutamine stress echocardiography may be useful with measurement of aortic velocity (or mean pressure gradient) and valve area at baseline and at higher flow rates (maximum dose dobutamine 20 mcg/kg per minute) under appropriate clinical and hemodynamic monitoring. Severe AS is characterized by a fixed valve area, resulting in an increase in transaortic velocity to ≥4 m/s (mean gradient ≥40 mm Hg) at any flow rate, but with valve area remaining ≤1.0 cm². In contrast, in patients with moderate AS and primary LV dysfunction, there is an increase in valve area as volume flow rate increases, resulting in only a modest increase in transaortic velocity or gradient. Some patients fail to show an increase in stroke volume ≥20% with dobutamine, referred to as “lack of contractile reserve” or “lack of flow reserve.”

4. The key measurements for clinical decision-making in patients with AS are the maximum aortic velocity, mean pressure gradient (calculated with the Bernoulli equation), and valve area (calculated with the continuity equation). An additional measurement that may be useful when there are discrepancies in these measures or in other clinical or imaging data is the ratio of the velocity in the LV outflow tract proximal to the aortic valve and the velocity in the narrowed aortic orifice. The outflow tract–to–aortic velocity ratio is independent of body size and eliminates potential errors in calculated valve area related to measurement of LV outflow tract diameter or area. A normal ratio is close to 1.0, whereas a ratio of ≤0.25 corresponds to a valve area 25% of normal for that patient, which is consistent with severe AS and is a predictor of symptom onset and adverse outcomes.

5. The degree of aortic valve calcification is a strong predictor of clinical outcome, even when evaluated qualitatively by echocardiography. Quantitation of aortic valve calcium by CT imaging is especially useful in patients with low-flow, low-gradient AS of unclear severity with either a normal or reduced LVEF. Sex-specific Agaston unit thresholds for diagnosis of severe AS are 1300 in women and 2000 in men. These different thresholds reflect the contribution of leaflet fibrosis, in addition to calcification, to increased leaflet stiffness in women. CT imaging also is used for procedural planning in patients undergoing TAVI, for measurement of annulus area, leaflet length, and the annular–to–coronary ostial distance.

3.2.1.2. Diagnostic Testing: Changing Signs or Symptoms
In patients with known valvular AS, repeat TTE is prudent when physical examination shows an increase in the loudness of the murmur, the murmur peaks later in systole, the A2 component of the second heart sound is diminished or absent, or symptoms occur that might be attributable to AS. Repeat TTE is also appropriate in patients with AS who are exposed to increased hemodynamic demands, either electively, such as with noncardiac surgery or pregnancy, or acutely, such as with a systemic infection, anemia, or gastrointestinal bleeding. In these clinical settings, knowledge of the severity of valve obstruction and LV function is critical for optimizing loading conditions and maintaining a normal cardiac output.

3.2.1.3. Diagnostic Testing: Routine Follow-Up
Timing of periodic clinical evaluation of asymptomatic patients with severe AS depends on comorbidities and patient-specific factors, as well as AS severity (Table 4). When severe AS is present (aortic velocity ≥4.0 m/s), the rate of progression to symptoms is high, with an event-free survival rate of only 30% to 50% at 2 years. In patients with asymptomatic severe AS, periodic monitoring is needed because symptom onset is insidious and may not be recognized by the patient. With moderate AS (aortic velocity 3.0–3.9 m/s), the average annual rate of progression is an increase in velocity of 0.3 m/s, increase in mean pressure gradient of 7 mm Hg, and decrease in valve area of 0.1 cm². There is marked individual variability, with more rapid progression in older patients and in patients with more severe leaflet calcification. In patients with aortic sclerosis, defined as focal areas of valve calcification and leaflet thickening with an aortic velocity <2.0 m/s, progression to severe AS occurs in about 10% of patients within 5 years. Patients with BAV disease are also at risk of progressive valve stenosis, with AS being the most common reason for intervention in patients with a BAV (Section 5.1.1).

3.2.1.4. Diagnostic Testing: Cardiac Catheterization
Diagnostic TTE and Doppler data can be obtained in nearly all patients, but severity of AS may be underestimated if image quality is poor or if a parallel intercept angle is not obtained between the ultrasound beam and aortic jet. When data from noninvasive testing are non-diagnostic or if there is a discrepancy between clinical and echocardiographic evaluation, cardiac catheterization for determination of severity of AS can be helpful. Transaortic pressure gradient recordings allow measurement of the mean transaortic gradient via simultaneous LV and aortic pressure measurements. Aortic valve area
is calculated with the Gorlin formula by using a Fick or thermodilution cardiac output measurement. See Section 14.1 for recommendations on coronary angiography in patients with AS.1,2

### 3.2.1.5. Diagnostic Testing: Exercise Testing

<table>
<thead>
<tr>
<th>Recommendations for Diagnostic Testing: Exercise Testing In Patients With AS</th>
<th>Referenced studies that support the recommendations are summarized in Online Data Supplement 4.</th>
</tr>
</thead>
<tbody>
<tr>
<td>COR</td>
<td>LOE</td>
</tr>
<tr>
<td>2a</td>
<td>B-NR</td>
</tr>
<tr>
<td>3: Harm</td>
<td>B-NR</td>
</tr>
</tbody>
</table>

**Synopsis**

In a subset of asymptomatic patients with severe AS, exercise testing can provide additional diagnostic and prognostic information, but it should not be performed in symptomatic patients with severe AS.

### Recommendation-Specific Supportive Text

1. When performed under the direct supervision of an experienced clinician, with close monitoring of blood pressure and ECG, exercise testing in asymptomatic patients is relatively safe and may provide information that is not evident during the initial clinical evaluation, particularly when the patient’s functional capacity is unclear. Patients with symptoms provoked by exercise testing should be considered symptomatic, even if the clinical history is equivocal. Although it can be challenging to separate normal exercise limitations from abnormal symptoms that are attributable to AS, particularly in elderly sedentary patients, exercise-induced angina, excessive dyspnea early in exercise, dizziness, and syncope are consistent with symptoms of AS. Exercise testing can also identify a limited exercise capacity or an abnormal blood pressure response. Recording aortic valve hemodynamics with exercise is of limited value and does not show additive value for predicting clinical outcome when baseline measures of hemodynamic severity and functional status are considered. In addition, recording hemodynamics with exercise is challenging, and simpler parameters are adequate in most patients.2-4,6-11

2. As reported in several prospective and retrospective studies, the risk of exercise testing is low in asymptomatic patients with AS. However, exercise testing is avoided in symptomatic patients with AS because of a high risk of complications, including syncope, ventricular tachycardia, and death. In a prospective survey of 20 medical centers in Sweden that included 50,000 exercise tests done over an 18-month period, the complication rate was 18.4 per 10,000 tests; morbidity rate, 5.2 per 10,000 tests; and mortality rate, 0.4 per 10,000 tests. Although the number of patients with AS was not reported, 12 of the 92 complications occurred in patients with AS: 8 had a decline in blood pressure during exercise, 1 had asystole, and 3 had ventricular tachycardia.2,4,5,7-10,12

### 3.2.2. Medical Therapy

**Synopsis**

Medical treatment of hypertension and hyperlipidemia according to GDMT is appropriate for patients with AS. ACE inhibitor or ARB treatment may reduce the mortality rate in patients with AS who underwent TAVI.

**Recommendation-Specific Supportive Text**

1. Hypertension is common in patients with AS, may be a risk factor for AS, and adds to the total pressure overload on the LV in combination with valve obstruction. Concern that antihypertensive medications might result in a decrease in cardiac output has not been corroborated in studies of medical therapy, including 2 small RCTs, likely because AS does not result in “fixed” valve obstruction until late in the disease process. In 1616 patients...
with asymptomatic AS in the SEAS (Simvastatin Ezetimibe in Aortic Stenosis) study, hypertension (n=1340) was associated with a 56% higher rate of ischemic cardiovascular events and a 2-fold higher mortality rate (both P<0.01) than those seen in normotensive patients with AS, although no impact on progression of valve stenosis leading to symptoms requiring AVR was seen. Medical therapy for hypertension follows standard guidelines, starting at a low dose and gradually titrating upward as needed to achieve blood pressure control. There are no studies addressing specific anti-hypertensive medications in patients with AS, but diuretics may reduce stroke volume, particularly if the LV chamber is small at baseline. In theory, ACE inhibitors may be advantageous because of the potential beneficial effects on LV fibrosis, in addition to control of hypertension. Consideration should be given to a higher target blood pressure for patients with AS than is recommended for the general population, but this is an underexplored area, and further data are needed before a different target blood pressure can be recommended for patients with AS.13–9–13

2. Concurrent CAD is common in patients with AS, and all patients should be screened and treated for hypercholesterolemia, with GDMT used for primary and secondary prevention of CAD. In RCTs of statin therapy for mild to moderate AS, although aortic valve event rates were not reduced, the rate of ischemic events was reduced by about 20% in the statin therapy group even though these patients did not meet standard criteria for statin therapy.6–8–14–15

3. In patients undergoing TAVI, observational and registry data show that those who were treated with renin–angiotensin system blocker therapy after the procedure had a lower 1-year mortality rate than those not treated with renin–angiotensin system blocker therapy, with a relative risk reduction of about 20% to 50% and an absolute risk reduction between 2.4% and 5.0%. When stratified by LVEF, having a prescription for a renin–angiotensin system inhibitor, versus no prescription, was associated with a lower 1-year mortality rate among patients with preserved LVEF but not among those with reduced LVEF.7,8,16,17

4. Despite experimental models and retrospective clinical studies suggesting that lipid-lowering therapy with a statin might prevent disease progression of calcific AS, 3 large well-designed RCTs failed to show a benefit, either in terms of changes in hemodynamic severity or in clinical outcomes, in patients with mild to moderate valve obstruction. Thus, at the time of publication, there are no data to support the use of statins for prevention of progression of AS.7,8,16,17

### 3.2.3. Timing of Intervention

**Recommendations for Timing of Intervention of AS**

**Synopsis**

See the table of recommendations for a summary of recommendations from this section and Figure 2 for indications for AVR in patients with AS. These recommendations for timing of intervention for AS apply to both SAVR and TAVI. The integrative approach to assessing risk of SAVR or TAVI is discussed in Section 2.5. The specific type of intervention for AS is discussed in Section 3.2.4.
CLINICAL STATEMENTS AND GUIDELINES

Recommendation-Specific Supportive Text

1. In symptomatic patients with severe high-gradient AS (Stage D1), ample evidence demonstrates the beneficial effects of AVR on survival, symptoms, and LV systolic function. The most common initial symptom of AS is exertional dyspnea or decreased exercise tolerance. Clinical vigilance is needed to recognize these early symptoms and proceed promptly to AVR. More severe “classical” symptoms of AS, including HF, syncope, or angina, can be avoided by appropriate treatment at the onset of even mild symptoms. Outcomes after surgical or transcatheter AVR are excellent in patients who do not have a high procedural risk. Surgical series demonstrate improved symptoms after AVR, and most patients have an improvement in exercise tolerance, as documented in studies with pre- and post-AVR exercise stress testing. Historical observation studies on outcomes in symptomatic patients with severe AS have been confirmed in RCTs comparing TAVI with palliative care in patients with a prohibitive surgical risk. The choice of surgical versus transcatheter AVR for patients with an indication for AVR is discussed in Section 3.2.4.1–3,5,6,12–16,35,42,47–55

2. In asymptomatic patients with severe AS and normal LV systolic function, the survival rate during the asymptomatic phase is similar to that of age-matched controls, with a low risk of sudden death (<1% per year) when patients are followed prospectively and when patients promptly report symptom onset. However, in patients with a low LVEF and severe AS, survival is better in those who undergo AVR than in those treated medically. The depressed LVEF in many patients is caused by excessive afterload (afterload mismatch), and LV function improves after AVR in such patients. If LV dysfunction is not caused
by afterload mismatch, survival is still improved, likely because of the reduced afterload with AVR, but improvement in LV function and resolution of symptoms might not be complete after AVR.17,23,24,56–62

3. Prospective clinical studies demonstrate that disease progression occurs in nearly all patients with severe asymptomatic AS. Symptom onset within 2 to 5 years is likely when aortic velocity is ≥4.0 m/s or mean pressure gradient is ≥40 mmHg. The additive risk of AVR at the time of other cardiac surgery is less than the risk of reoperation within 5 years.12–16,63–65

4. Mean pressure gradient is a strong predictor of outcome after AVR, with better outcomes seen in patients with higher gradients. Outcomes are poor with severe low-gradient AS but are still better with AVR than with medical therapy in those with a low LVEF, particularly when contractile reserve is present. The document “Echocardiographic Assessment of Valve Stenosis: EAE/ASE Recommendations for Clinical Practice” defines severe AS on dobutamine stress testing as a maximum velocity >4.0 m/s with a valve area ≤1.0 cm² at any point during the test protocol, with a maximum dobutamine dose of 20 mcg/kg per minute.66 The recommendation for AVR in these patients is based on outcome data in several prospective nonrandomized studies. LVEF typically increases by 10 LVEF units and may return to normal if afterload mismatch was the cause of LV systolic dysfunction. If dobutamine stress testing indicates moderate, not severe AS, GDMT for HF can be continued without AVR. Patients without contractile reserve may also benefit from AVR, but decisions in these high-risk patients must be individualized because outcomes are poor with either surgical or medical therapy. The role of TAVI in these patients is currently under investigation.17,22–24,59,60,67

5. A subset of patients with severe AS presents with symptoms and a low LV filling pressure, low LV stroke volume index, despite a normal LVEF. Low-flow, low-gradient severe AS with preserved LVEF should be considered in patients with a severely calcified aortic valve, an aortic velocity <4.0 m/s (mean pressure gradient <40 mmHg), and a valve area ≤1.0 cm² when stroke volume index is <35 mL/m². Typically, the LV is small, with thick walls, diastolic dysfunction, and a normal LVEF (≥50%). The first diagnostic step is to ensure that data were recorded and measured correctly. If hypertension is present, blood pressure is controlled before reevaluation of AS severity. Next, valve area is indexed to body size because an apparent small valve area may be only moderate AS in a small patient; an aortic valve area index ≤0.6 cm²/m² suggests severe AS. Transaortic stroke volume is calculated by Doppler or 2D imaging. Measurement of a CT calcium score often is helpful. Evaluation for other potential causes of symptoms ensures that symptoms are most likely attributable to valve obstruction. Although the survival rate after TAVI is lower in patients with low-flow severe AS than in patients with normal-flow severe AS, AVR appears beneficial, with an increase in stroke volume and improved survival as compared with medical therapy.18,25–27,54,68–70

6. Exercise testing may be helpful in clarifying symptom status in patients with severe AS. When symptoms are provoked by exercise testing, the patient is considered symptomatic and meets a COR 1 recommendation for AVR; symptoms are symptoms, whether reported spontaneously by the patient or provoked on exercise testing. The rate of symptom onset within 1 to 2 years is high (about 60% to 80%) in patients without overt symptoms who demonstrate 1) a fall of ≥10 mmHg in systolic blood pressure from baseline to peak exercise or 2) a significant decrease in exercise tolerance as compared with age and sex normal standards. Management of patients with a lack of appropriate rise in BP with exercise is less clear. Decisions about elective AVR in these patients include consideration of surgical risk, patient preferences, and clinical factors, such as age and comorbid conditions.13,28,77–82

7. In patients with very severe AS and an aortic velocity ≥5.0 m/s or mean pressure gradient ≥60 mmHg, the rate of symptom onset is approximately 50% at 2 years. On multivariable analysis of a large cohort of adults with asymptomatic AS (>500 patients), an aortic velocity ≥5 m/s was associated with a >6-fold increased risk of cardiovascular mortality (hazard ratio [HR]: 6.31; 95% CI: 2.61–15.9).33 A randomized trial of SAVR versus continued surveillance showed a significant survival benefit to early surgery in patients with aortic velocity ≥4.5 m/s.31 In patients with very severe asymptomatic AS and low surgical risk, a decision to proceed with AVR or continue watchful waiting takes into account patient age, avoidance of patient–prosthesis mismatch, anticoagulation issues, and patient preferences.31–33,39

8. An elevated serum BNP level is a marker of subclinical HF and LV decompensation. In a cohort of 387 asymptomatic adults with severe AS, elevated BNP levels were associated with an increased 5-year risk of AS-related events, with a
hazard ratio for a BNP level >300 pg/mL (3 times normal) of 7.38 (CI: 3.21 to 16.9).\textsuperscript{32} Serum BNP levels also are predictive of symptom onset during follow-up and persistent symptoms after AVR.\textsuperscript{36}

9. Hemodynamic progression eventually leading to symptom onset occurs in nearly all asymptomatic patients with AS once the aortic velocity reaches \( \geq 2 \) m/s. Although the average rate of hemodynamic progression for calcific stenosis of a trileaflet valve is an increase in aortic velocity of about 0.3 m/s per year, an increase in mean gradient of 7 to 8 mmHg per year, and a decrease in valve area of 0.15 cm\(^2\) per year, there is marked variability between patients in disease progression. Predictors of rapid disease progression include older age, more severe valve calcification, and a faster rate of hemodynamic progression on serial studies. In patients with an aortic velocity >4 m/s in addition to predictors of rapid disease progression, symptom onset is likely in the near future, so there is less benefit to waiting for symptom onset. Thus, elective AVR may be considered if the surgical risk is low and after consideration of other clinical factors and patient preferences.

10. In adults with initially asymptomatic severe AS, the rate of sudden death is low (<1% per year). However, an aortic velocity \( \geq 5 \) m/s or an LVEF <60% each is associated with higher all-cause and cardiovascular mortality rates in the absence of AVR.\textsuperscript{31} A multivariate analysis of predictors of death in a large cohort (>500 patients) showed a >4-fold higher risk of cardiovascular death for those with an LVEF <60% than for those with a higher LVEF (HR: 4.47; 95% CI: 2.06 to 9.70).\textsuperscript{33} A progressive decrease in LVEF is most likely in those with an LVEF <60% before AS becomes severe.\textsuperscript{8,9,11} Evaluation for other causes of a decline in LVEF is appropriate, particularly when AS is not yet severe, but a progressive decline in LV systolic function is of concern and should prompt more frequent evaluation, and consideration of AVR when repeat studies show a progressive decline in LVEF without other cause with medical therapy. The presence of at least 3 serial imaging studies showing a consistent decline in LVEF ensures that the changes seen are not simply attributable to recording, measurement, or physiological variability.\textsuperscript{8-11}

11. Hemodynamic progression eventually leading to symptom onset occurs in nearly all asymptomatic patients with AS. The survival rate during the asymptomatic phase is similar to age-matched controls, with a low risk of sudden death (<1% per year) when patients are followed prospectively and when patients promptly report symptom onset. The rate of symptom onset is strongly dependent on the severity of AS, with an event-free survival rate of about 75% to 80% at 2 years in those with a jet velocity <3.0 m/s, compared with only 30% to 50% in those with a jet velocity \( \geq 4.0 \) m/s. Patients with asymptomatic AS require periodic monitoring for development of symptoms and progressive disease (Section 3.1). In patients with moderate calcific AS undergoing cardiac surgery for other indications, the risk of progressive VHD is balanced against the risk of repeat surgery or TAVI (Sections 4.3.3 and 10). This decision must be individualized on the basis of the specific operative risk in each patient, clinical factors such as age and comorbid conditions, valve durability, and patient preferences.\textsuperscript{13,49,62-64}

**Synopsis**

Shared decision-making about the choice of prosthetic valve type is influenced by several factors,
including patient age, values, and preferences; expected bioprosthetic valve durability, avoidance of patient–prosthesis mismatch, and the potential need for and timing of reintervention; and the risks associated with long-term VKA anticoagulation with a mechanical valve replacement. Despite the significantly higher rate of bioprosthetic structural valve deterioration observed in younger versus older patients, many patients choose to avoid a mechanical prosthesis because they are unwilling to consider long-term VKA therapy because of the inconvenience of monitoring, dietary restrictions, medication interactions, and the need to restrict participation in some types of athletic activity. A mechanical valve might be a prudent choice for patients for whom a second surgical procedure would involve very high risk (eg, those with prior radiation exposure). The availability of TAVI has changed the dynamics of the discussion of the trade-offs between mechanical and bioprosthetic valves in younger patients (Table 22).

**Recommendation-Specific Supportive Text**

1. The choice of valve prosthesis in each patient is based on consideration of several factors, including valve durability, expected hemodynamics for valve type and size, surgical or interventional risk, the potential need for long-term anticoagulation, and patient values and preferences. The trade-off between the risk of reintervention for bioprosthetic valve deterioration and the risk of long-term anticoagulation should be discussed. Some patients prefer to avoid repeat surgery and are willing to accept the risks and inconvenience of lifelong anticoagulant therapy. Other patients are unwilling to consider long-term anticoagulation because of the inconvenience of monitoring, the attendant dietary and medication interactions, and the need to restrict participation in some types of physical activity. The incidence of structural deterioration of a bioprosthesis is greater in younger patients, but the risk of bleeding from anticoagulation is higher in older patients. In patients with shortened longevity and/or multiple comorbidities, a bioprosthesis might be more appropriate. In women who desire subsequent pregnancy, the issue of anticoagulation during pregnancy is an additional consideration (see pregnancy-related issues in Section 13.5).

2. Anticoagulant therapy with VKA is necessary in all patients with a mechanical valve to prevent valve thrombosis and thromboembolic events. If anticoagulation is contraindicated or if the patient refuses VKA therapy, an alternative valve choice is appropriate. Newer anticoagulant agents have not been shown to be safe or effective in patients with mechanical heart valves.

3. Patients <50 years of age at the time of AVR incur a higher and earlier risk of bioprosthetic valve deterioration. Overall, the predicted 15-year risk of needing reoperation because of structural deterioration is 22% for patients 50 years of age, 30% for patients 40 years of age, and 50% for patients 20 years of age, although it is recognized that all bioprostheses are not alike in terms of durability. Anticoagulation with a VKA can be accomplished with acceptable risk in most patients <50 years of age, particularly in compliant patients with appropriate monitoring of INR levels. Thus, the balance between valve durability and risk of bleeding and thromboembolic events favors the choice of a mechanical valve in patients <50 years of age, unless anticoagulation is not desired, cannot be monitored, or is contraindicated.

4. Uncertainty and debate continue about which type of AVR is appropriate for patients 50 to 65 years of age. Newer surgical bioprosthetic valves may show greater freedom from structural deterioration, specifically in the older individual, although a high late mortality rate in these studies may preclude recognition of valve dysfunction. The risks of bleeding and thromboembolism with mechanical prostheses are low, especially in compliant patients with appropriate INR monitoring. Several studies have shown a survival advantage with a mechanical prosthesis in this age group. Alternatively, large retrospective observational studies have shown similar long-term survival rates in patients 50 to 69 years of age undergoing mechanical versus bioprosthetic valve replacement. In general, patients with mechanical valves experience a higher risk of bleeding caused by anticoagulation, whereas individuals who receive bioprosthetic valves experience a higher rate of reoperation because of structural deterioration of the prosthesis, as well as perhaps a decrease in survival rate. There are several other factors to consider in the choice of type of valve prosthesis (see Section 11.1).

5. In patients >65 years of age at the time of bioprosthetic AVR, the likelihood of primary structural deterioration at 15 to 20 years is only about 10%. In addition, older patients are at higher
risk of bleeding complications related to VKA therapy and more often require interruption of VKA therapy for noncardiac surgical and interventional procedures. It is reasonable to use a bioprosthetic valve in patients >65 years of age to avoid the risks of anticoagulation because the durability of the valve exceeds the expected years of life.

6. Replacement of the aortic valve with a pulmonary autograft (the Ross procedure) is a complex operation involving replacement of the aortic valve by the patient’s own pulmonic valve, along with placement of a pulmonic valve homograft. The Ross procedure allows the patient to avoid a prosthetic heart valve and the risks of anticoagulation and it provides excellent valve hemodynamics. However, both the pulmonic homograft in the pulmonic position and the pulmonary autograft (the neoaortic valve) are at risk of valve degeneration. The failure of the Ross procedure is most often attributable to regurgitation of the neoaortic valve in the second decade after the operation. In addition, at least half of pulmonic homograft valves require reintervention within 10 to 20 years. Calcification of the homograft and adhesions between the homograft and neoaorta may increase the difficulty of reoperation. The Ross procedure typically is reserved for younger patients with appropriate anatomy and tissue characteristics for whom anticoagulation is either contraindicated or undesirable, and it is performed only at Comprehensive Valve Centers by surgeons experienced in this procedure.13–15

3.2.4.2. Choice of SAVR Versus TAVI for Patients for Whom a Bioprosthetic AVR Is Appropriate (Continued)

<td></td>
</tr>
</tbody>
</table>

**Synopsis**

In patients considering a bioprosthetic AVR, the next step is the choice between SAVR and TAVI. In patients with a high or prohibitive risk for SAVR (see Section 2.5), decision-making focuses on TAVI versus palliative care. When surgical risk is not high or prohibitive, procedure-specific impediments are assessed (Figure 3). When both SAVR and TAVI are options, a prime consideration is the limited data about TAVI durability. SAVR has been used for more than 50 years, with ample durability data available for specific valve types across different age groups. Currently, robust durability data for TAVI extend to only about 5 years. SAVR valve deterioration typically occurs after >10 years, so longer-term TAVI durability data are needed. A key factor in decision-making is the ratio of patient life expectancy to known valve durability, with patient age often used as a surrogate for life expectancy. For a woman in the United States, the average additional expected years of life are 25 at age 60 years, 17 at age 70 years, and 10 at age 80 years. For a man, expected additional years of life are 22 at age 60 years, 14 at age 70 years, and 8 at age 80 years. The age breakpoints shown in these recommendations reflect these.

</table>
Figure 3. Choice of SAVR versus TAVI when AVR is indicated for valvular AS.

Colors correspond to Table 2. *Approximate ages, based on US Actuarial Life Expectancy tables, are provided for guidance. The balance between expected patient longevity and valve durability varies continuously across the age range, with more durable valves preferred for patients with a longer life expectancy. Bioprosthetic valve durability is finite (with shorter durability for younger patients), whereas mechanical valves are very durable but require lifelong anticoagulation. Long-term (20-y) data on outcomes with surgical bioprosthetic valves are available; robust data on transcatheter bioprosthetic valves extend to only 5 years, leading to uncertainty about longer-term outcomes. The decision about valve type should be individualized on the basis of patient-specific factors that might affect expected longevity. †Placement of a transcatheter valve requires vascular anatomy that allows transfemoral delivery and the absence of aortic root dilation that would require surgical replacement. Valvular anatomy must be suitable for placement of the specific prosthetic valve, including annulus size and shape, leaflet number and calcification, and coronary ostial height. See ACC Expert Consensus Statement.20 AS indicates aortic stenosis; AVR, aortic valve replacement; LVEF, left ventricular ejection fraction; QOL, quality of life; SAVR, surgical aortic valve replacement; STS, Society of Thoracic Surgeons; TAVI, transcatheter aortic valve implantation; TF, transfemoral; and VKA, vitamin K antagonist.
statistical averages and serve as the starting point for shared decision-making, not as absolute values for chronological age. Some younger patients with comorbid conditions have a limited life expectancy, whereas some older patients have a longer-than-average life expectancy. Decision-making should be individualized on the basis of patient-specific factors that affect longevity or quality of life, such as comorbid cardiac and noncardiac conditions, frailty, dementia, and other factors. In addition, the choice of implantation approach is based on a shared decision-making process that accounts for the patient's values and preferences and includes discussion of the indications for and against each approach and the potential need for and risks associated with valve reintervention.  

Recommendation-Specific Supportive Text

1. SAVR has demonstrated excellent durability and outcomes for both mechanical and bioprosthetic valves. Earlier RCTs comparing SAVR and TAVI in patients with a higher surgical risk included only older patients, with a mean age in the mid-80s. More recent RCTs that included patients at low to intermediate surgical risk had a mean age in the mid-70s, but there were very few patients <65 years of age, so the evidence base cannot be extrapolated to these patients. In addition, valve durability is of higher priority in younger patients, who typically have a longer life expectancy and lower surgical risk. As longer-term data on TAVI valve durability become available, the age range for recommending TAVI may shift, but at this time the most prudent course, based on the published evidence, is to recommend SAVR for adults <65 years of age unless life expectancy is limited by comorbid cardiac or noncardiac conditions. The final choice of implantation approach is based on a shared decision-making process that accounts for the patient's values and preferences and includes discussion of the indications for and against each approach and the potential need for and risks associated with valve reintervention. There are no data for the use of TAVI in patients <65 years of age.  

2. Both SAVR and TAVI are effective approaches to AVR in adults 65 to 80 years of age. Patients enrolled in RCTs of TAVI versus SAVR had high-velocity severe AS (Stage D1). However, less robust data from observational studies and registry data are encouraging with regard to TAVI for symptomatic patients with low-flow, low-gradient severe AS (Stages D2 and D3). Thus, these guidelines make the same recommendations for symptomatic patients with confirmed severe AS regardless of flow rate. TAVI has a slightly lower mortality risk and is associated with a shorter hospital length of stay, more rapid return to normal activities, lower risk of transient or permanent AF, less bleeding, and less pain than SAVR. On the other hand, SAVR is associated with a lower risk of paravalvular leak, less need for valve reintervention, and less need for a permanent pacemaker. When the choice of SAVR or TAVI is being made in an individual patient between 65 and 80 years of age, other factors, such as vascular access, comorbid cardiac and noncardiac conditions that affect risk of either approach, expected functional status and survival after AVR, and patient values and preferences, must be considered. The choice of mechanical or bioprosthetic SAVR (Section 11) versus a TAVI is an important consideration and is influenced by durability considerations, because durability of transcatheter valves beyond 5 to 6 years is not yet known.

3. TAVI is a safe and effective procedure for treatment of severe symptomatic AS in all adults regardless of estimated surgical risk. The mortality rate for transfemoral TAVI is lower than that for SAVR, with a HR of 0.88 and a 95% CI of 0.78 to 0.99 in a meta-analysis of RCTs. TAVI also is associated with a lower risk of stroke (HR: 0.81; 95% CI: 0.68–0.98; P=0.028), major bleeding, and AF, as well as a shorter hospital length of stay, less pain, and more rapid return to normal activities. Compared with SAVR, TAVI results in higher rates of vascular complications, paravalvular regurgitation, permanent pacemaker implantation, and valve intervention, but most patients will consider that the advantages of TAVI outweigh these disadvantages. TAVI valves are durable to at least 5 years, and the limited data on TAVI durability are of less concern to most patients >80 years of age because the valve durability is likely to be longer than the patient's life expectancy. If significant valve deterioration does occur, a second TAVI within the first prosthesis, (called a valve-in-valve TAVI), is likely to be possible. When a transfemoral approach is not possible, other factors, such as alternative vascular access, comorbid cardiac and noncardiac conditions, expected functional status and survival after AVR, and patient values and preferences, must be considered. The specific choice of a balloon-expandable valve or self-expanding valve depends on patient anatomy and other considerations.

4. An LVEF <50% in a patient with severe AS is a COR 1 indication for AVR, so the choice of TAVI versus SAVR in these patients is based on the same considerations as in patients with symptoms...
attributable to severe AS. From a pathophysiological point of view, the reasons for thinking that TAVI might be especially beneficial with severe AS and a low LVEF are the avoidance of myocardial ischemia with an open surgical procedure and the greater reduction in afterload with a larger effective valve area. However, outcome data from RCTs show that a low LVEF also is a risk factor for adverse outcomes even with TAVI. The final choice of implantation approach is based on a shared decision-making process that accounts for the patient's values and preferences and includes discussion of the indications for and against each approach and the potential need for and risks associated with valve reintervention. Studies on the potential benefit of TAVI in patients with moderate AS and LV systolic dysfunction are in progress.

5. Published RCTs comparing TAVI and SAVR included only patients with symptoms attributable to severe AS. Asymptomatic patients with COR 2a indications for AVR should either undergo SAVR or wait until a COR 1 indication is present before intervention. The recommendation for SAVR in preference to TAVI includes asymptomatic patients for whom AVR is being considered because of an abnormal exercise blood pressure response, an elevated serum BNP level, rapid hemodynamic progression, or very severe AS with a velocity of ≥5 m/s. The final choice of implantation approach is based on a shared decision-making process that accounts for the patient's values and preferences and includes discussion of the indications for and against each approach and the potential need for and risks associated with valve reintervention.

6. Published RCTs have focused primarily on TAVI via the transfemoral vascular access route. The mortality rate has been higher with TAVI by nonfemoral access routes than with SAVR, possibly because of the access approach itself, but more likely because of the higher comorbidity burden and risk in patients with vascular disease severe enough to preclude transfemoral access. When transfemoral TAVI is not feasible, SAVR or palliative care options should be included in the shared decision-making discussion. The final choice of implantation approach is based on a shared decision-making process that accounts for the patient's values and preferences and includes discussion of the indications for and against each approach and the potential need for and risks associated with valve reintervention.

7. TAVI was compared with standard medical therapy in a prospective RCT of patients with severe symptomatic AS who were deemed inoperable. The rate of all-cause death at 2 years was lower with TAVI (43.3%) (HR: 0.58; 95% CI: 0.36–0.92; \( P = 0.02 \)) than with standard medical therapy (68%). Standard therapy included percutaneous aortic balloon dilation in 84%. There was a reduction in repeat hospitalization with TAVI (55% versus 72.5%; \( P < 0.001 \)). In addition, only 25.2% of survivors were in New York Heart Association (NYHA) class III or IV 1 year after TAVI, compared with 58% of patients receiving standard therapy (\( P < 0.001 \)). However, the rate of major stroke was higher with TAVI than with standard therapy at 30 days (5.05% versus 1.0%; \( P = 0.06 \)) and remained higher at 2 years (13.8% versus 5.5%; \( P = 0.01 \)). Major vascular complications occurred in 16.2% with TAVI versus 1.1% with standard therapy (\( P < 0.001 \)). Similarly, in a nonrandomized study of 489 patients with severe symptomatic AS and extreme surgical risk treated with a self-expanding TAVI valve, the rate of all-cause death at 12 months was 26% with TAVI, compared with an expected mortality rate of 43% if patients had been treated medically. The final choice of TAVI versus palliative care is based on a shared decision-making process that accounts for the patient's values and preferences and includes discussion of the indication, risks, and benefits for and against each approach.

8. The survival and symptom reduction benefit of TAVI is seen only in appropriately selected patients. Baseline clinical factors associated with a poor outcome after TAVI include advanced age, frailty, smoking or chronic obstructive pulmonary disease, pulmonary hypertension, liver disease, prior stroke, anemia, and other systemic conditions. The STS estimated surgical risk score provides a useful measure of the extent of patient comorbidities and may help identify which patients will benefit from TAVI. Patients with a mechanical impediment to SAVR, such as a porcelain aorta or prior chest radiation damage, may have better outcomes after TAVI than do frail patients or those with moderate to severe disease in more than one other organ system. The likely benefits and risks of TAVI are considered in weighing the risk–benefit ratio of intervention in an individual patient. TAVI is not recommended in patients with 1) a life expectancy of <1 year even with a successful procedure or 2) those with a chance of “survival with benefit” of <25% at 2 years.
9. Percutaneous aortic balloon dilation has a role in treating children, adolescents, and young adults with AS, but its role in treating older patients is very limited. The mechanism by which balloon dilation modestly reduces the severity of stenosis in older patients is fracture of calcific deposits within the valve leaflets and, to a minor degree, stretching of the annulus and separation of the calcified or fused commissures. Immediate hemodynamic results include a

</tbody>
</table>

*Expected remaining years of life can be estimated from US Actuarial Life Expectancy tables. The balance between expected patient longevity and valve durability varies continuously across the age range, with more durable valves preferred for patients with a longer life expectancy. Bioprosthetic valve durability is finite (with shorter durability for younger patients), whereas mechanical valves are very durable but require lifelong anticoagulation. Long-term (20-y) data on outcomes with surgical bioprosthetic valves are available; robust data on transcatheter bioprosthetic valves extend only to 5 y, leading to uncertainty about longer-term outcomes. The decision about valve type should be individualized on the basis of patient-specific factors that might affect expected longevity.

TAVI large aortic annulus may not be suitable for currently available transcatheter valve sizes. With a small aortic annulus or aorta, a surgical annulus-enlarging procedure may be needed to allow placement of a larger prosthesis and avoid patient–prosthesis mismatch.

†Dilation of the aortic sinuses or ascending aorta may require concurrent surgical replacement, particularly in younger patients with a BAV.

‡Dilation of the aortic sinuses or ascending aorta may require concurrent surgical replacement, particularly in younger patients with a BAV.

Modified from Burke et al.14
4. AORTIC REGURGITATION

4.1. Acute Aortic Regurgitation

Acute aortic regurgitation (AR) may result from abnormalities of the valve, most often endocarditis, or abnormalities of the aorta, primarily aortic dissection. Acute AR may also occur as an iatrogenic complication of a transcatheter procedure or after blunt chest trauma. The acute volume overload on the LV usually results in severe pulmonary congestion, as well as a low forward cardiac output. Urgent diagnosis and rapid intervention are lifesaving.

4.1.1. Diagnosis of Acute AR

TEE or TEE is indispensable in confirming the presence, severity, and etiology of acute AR; determining whether there is rapid equilibration of the aortic and LV diastolic pressures; visualizing the aortic root; and evaluating LV size and systolic function. A short deceleration time on the aortic flow velocity curve and early closure of the mitral valve are indicators of markedly elevated LV end-diastolic pressure. A pressure half-time of <300 ms on the AR velocity curve indicates rapid equilibration of the aortic and LV diastolic pressures. The degree of holodiastolic flow reversal in the aortic arch, in comparison with the forward systolic flow, provides a quick semiquantitative estimate of regurgitant fraction. Acute severe AR caused by aortic dissection is a surgical emergency.

CT imaging is the primary approach for diagnosis of acute aortic dissection because it is highly accurate and continuously available at most medical centers. MRI is rarely used in the acute setting because of patient instability. TEE may be used when CT imaging is unavailable and is helpful in intraoperative assessment of aortic valve function before and after the surgical intervention. The sensitivity and specificity of TTE for diagnosis of Type A aortic dissection are only 60% to 80%, whereas TEE has a sensitivity of 98% to 100% and a specificity of 95% to 100%. Angiography should be considered only when the diagnosis cannot be determined by noninvasive imaging or when the differential diagnosis is an acute coronary syndrome.

4.1.2. Intervention for Acute AR

In patients with acute severe AR resulting from IE or aortic dissection, medical therapy to reduce LV afterload may allow temporary stabilization, but surgery should not be delayed, especially if there is hypotension, pulmonary edema, or evidence of low flow. Intra-aortic balloon counterpulsation is contraindicated in patients with acute severe AR. Beta blockers are often used in treating aortic dissection. However, these agents should be used very cautiously, if at all, for other causes of acute AR because they will block the compensatory tachycardia and could precipitate a marked reduction in blood pressure.

4.2. Stages of Chronic AR

The most common causes of chronic severe AR in the United States and other high-income countries are BAV disease and primary diseases of the ascending aorta or the sinuses of Valsalva. Rheumatic heart disease is the leading cause of AR in many low- to middle-income countries. With calcific valve disease, regurgitation often accompanies AS, but the degree of regurgitation usually is mild to moderate, not severe. In most patients with AR, the disease course is chronic and slowly progressive, with increasing LV volume overload and LV adaptation via chamber dilation and hypertrophy. Management of patients with AR depends on an accurate diagnosis of the cause and stage of the disease process. Table 15 shows the stages of AR, ranging from patients at risk of AR (Stage A) or with progressive mild to moderate AR (Stage B) to severe asymptomatic (Stage C) and symptomatic (Stage D) AR. Each of these stages is defined by valve anatomy, valve hemodynamics, severity of LV dilation, and LV systolic function, as well as by patient symptoms.

</tr>
</tbody>
</table>

Synopsis

TTE provides diagnostic information about the etiology and mechanism of AR (including valve reparablelity), severity of regurgitation, morphology of the ascending aorta, and LV response to the increases in preload and afterload. Imaging with TEE, CMR, or aortic angiography provides additional information when needed.

Recommendation-Specific Supportive Text

1. Although qualitative measures of AR severity are adequate in many situations, when AR is significant (Stages B and C), quantitative measures of regurgitant volume and effective regurgitant orifice (ERO) area1 are better predictors of clinical outcome.2,3 Measures of LV systolic function (LVEF or fractional shortening) and LV end-systolic dimension (LVEDD) or LV end-systolic volume are predictive of the development of HF symptoms or death in initially asymptomatic patients (Stages B and C) and are significant determinants of survival and functional results after surgery in asymptomatic and symptomatic patients (Stages C2 and D).2-18,20 Symptomatic patients (Stage D) with normal LVEF have a significantly better long-term postoperative survival rate than those with depressed systolic function.

2. Auscultation has high specificity for detecting AR but low sensitivity and diagnostic accuracy.27 TTE can identify AR in patients who have been deemed to be at risk on the basis of the presence of known aortic dilation or a condition associated with abnormal aortic valve function, such as a BAV.

3. TTE and CMR are useful for evaluating patients in whom there is discordance between clinical assessment and severity of AR by TTE or when TTE images are suboptimal. CMR imaging provides accurate and reproducible measures of regurgitant volume and regurgitant fraction in patients with AR, as well as assessment of aortic morphology, LV volume, and LV systolic function. Cardiac catheterization with LV and aortic angiography, as well as quantitation of regurgitation severity, is another option.20-25,28-30

</tr>
</tbody>
</table>

Synopsis

There is no evidence that vasodilating drugs reduce severity of AR or alter the disease course in patients with significant AR in the absence of systemic hypertension. Recommendations for GDMT for hypertension and HF apply to patients with chronic asymptomatic AR, as for the general population.

Recommendation-Specific Supportive Text

1. Severe AR is associated with a wide pulse pressure, such that systolic blood pressure is higher than in patients without AR even when systemic vascular resistance is normal. Transaortic stroke volume increases further with medications that lower heart rate, such as beta blockers, which may result in a paradoxical apparent increase in blood pressure. Vasodilating drugs, such as ACE inhibitors or ARBs, do not affect heart rate and thus may reduce systolic blood pressure without a substantial reduction in diastolic blood pressure in patients with chronic AR.1,2,5-8

2. In symptomatic patients who are candidates for surgery, medical therapy is not a substitute for AVR. However, medical therapy is helpful for alleviating symptoms in patients who are considered to be at very high surgical risk because of concomitant comorbid medical conditions.5,9
SYNOPSIS

Most patients with indications for surgery for chronic severe AR require valve replacement with a mechanical or bioprosthetic valve (Figure 4). Preservation of the native aortic valve (“valve sparing”) may be possible in selected patients with favorable valve anatomy who are undergoing surgical replacement of the aortic sinuses and/or ascending aorta.33–39 Although advancements are occurring in primary aortic valve repair,37,40–42 this approach is not yet generalizable, and durability is not known. Current recommendations for AVR related to severity of LV dilation are based on measurement of LV short-axis diameters. There are limited data demonstrating prognostic value of LV volume measurements in chronic AR using left ventriculography,43 2D echocardiography,18,44 and CMR.45,46 Normal limits for LV volumes have been determined, as have criteria for severe LV dilation, but these values differ between 2D echocardiography, 3D echocardiography, and CMR,47,48 and there are insufficient data on the relationship between LV volumes and outcomes of patients with AR. This is an area in need of further investigation. Other markers of LV dysfunction and remodeling, such as global longitudinal strain and circulation biomarkers,44,46,48–51 likewise require additional clinical outcome studies.

Recommendation-Specific Supportive Text

1. Symptoms are an important indication for AVR in patients with chronic severe AR, and the most important aspect of the clinical evaluation is taking a careful, detailed history to elicit symptoms or diminution of exercise capacity. Patients with chronic severe AR who develop symptoms have a high risk of death if AVR is not performed,52 and survival and functional status after AVR are related to the severity of preoperative symptoms, assessed either subjectively or objectively with exercise testing.1–4 Even among symptomatic patients with a severe reduction in LVEF (<35%), AVR results in improved survival rate.5–7

2. LV systolic function is an important determinant of survival and functional status after AVR.3–5,8,9,12,53–61 Outcomes are optimal when surgery is performed before LVEF decreases below 55%,16,25,26. In asymptomatic patients with LV systolic dysfunction, postoperative outcomes are better if AVR is performed before onset of symptoms.53

3. Patients with chronic severe AR may be referred for other types of cardiac surgery, such as CABG, mitral valve surgery, or surgery for correction of dilation of the aortic root or ascending aorta. In these patients, AVR will prevent both the hemodynamic consequences of persistent AR during the perioperative period and the possible need for a second cardiac operation in the near future. Patients undergoing surgical repair or replacement of the aortic root or ascending aorta may be candidates for aortic valve-sparing procedures.33–39

4. LVESD in patients with chronic AR reflects both the severity of the LV volume overload and the degree of LV systolic shortening.54,62 An elevated LVESD often reflects LV systolic dysfunction with a depressed LVEF. If LVEF is normal, an increased LVESD indicates a significant degree of LV remodeling and is associated with subsequent development of symptoms and/or LV systolic dysfunction and an increased mortality rate after AVR.17,20,21 Most studies have used unadjusted LVESD, but indexing for body size is important, particularly in women or small patients.13,19,52 Recent data indicate that the LVESD index threshold for optimal postoperative survival may be even smaller than 25 mm/m²14–16 but more outcome data, and ideally an RCT, of earlier intervention are needed.
LV volumes may be a more sensitive predictor of cardiac events than LVESD index in asymptomatic patients, but more data are needed to determine the threshold values of LV systolic volume that best predict postoperative outcomes.

5. In patients with moderate AR who are undergoing other forms of cardiac surgery, such as CABG, mitral valve surgery, or replacement of the ascending aorta, the decision to intervene on the aortic valve concurrently includes consideration of several factors, including aortic valve anatomy, aortic root size and shape, regurgitant severity, other comorbidities, and patients’ preferences and values. Patients undergoing surgical repair or replacement of the aortic root or ascending aorta may be candidates for a valve-sparing procedure.

6. LVEDD, a marker of the severity of LV volume overload in patients with chronic AR, is significantly associated with clinical outcomes in asymptomatic patients, and progressive increases in LVEDD are associated with subsequent need for surgery. In asymptomatic patients, it is important to ensure that apparent changes in LV size or LVEF are not due simply to measurement or physiological variability. In addition, confirmation of severe regurgitation by quantitative measures of AR severity with TTE, TEE, or, when needed, CMR provides confidence that AR is the cause of LV dilation or decrease in LVEF. When there is an apparent significant fall in EF or increase in LV size, repeat imaging typically is performed at 3- to 6-month intervals unless there is clinical deterioration.

7. TAVI for isolated chronic AR is challenging because of dilation of the aortic annulus and aortic root and, in many patients, lack of sufficient leaflet calcification. Risks of TAVI for treatment of AR include transcatheter valve migration and significant paravalvular leak. TAVI is rarely feasible, and then only in carefully selected patients with severe AR and HF who have a prohibitive surgical risk and in whom valvular calcification and annular size are appropriate for a transcatheter approach.

</tr>
</tbody>
</table>

Synopsis

BAV is a common congenital anomaly that affects 0.5% to 2.0% of adults with a 3:1 male-to-female predominance. Patients with BAV may develop isolated aortic valve disease, including isolated AR, AS, or a combination of the two. Aortic aneurysms have been reported in 20% to 40% of patients with BAV. This aortopathy can occur independent of valve function and consists of dilation of the aortic sinuses, the ascending aorta, or the arch. Therefore, patients with BAV require careful evaluation of both the aortic valve and the aorta throughout their lifetimes (Figure 5).

Recommendation-Specific Supportive Text

1. Many patients with BAV will develop AS or AR over their lifetimes. In a recent meta-analysis of natural history studies of patients with BAV, 13% to 30% of patients developed moderate or greater AR and 12% to 37% developed moderate or greater AS during follow-up. TTE usually is adequate for evaluation of aortic valve anatomy and hemodynamics. TEE provides improved 2D and 3D images if needed. Aortic enlargement at the level of the sinuses or proximal ascending aorta has been reported in 20% to 40% of patients with BAV, and some develop severe aneurysmal dilation and are at increased risk of aortic dissection. Aortic measurements are reported at the aortic annulus, sinuses of Valsalva, sinotubular junction, and mid-ascending aorta. Doppler interrogation of the proximal descending aorta and abdominal aorta should also be performed to evaluate for the presence of aortic coarctation, which is associated with BAV in a subset of patients, although a coarctation also can be detected by comparing arm and leg blood pressures.

2. CT angiography or CMR provides better images of the aortic sinuses, sinotubular junction, or ascending aorta when TTE does not adequately visualize the sinus and proximal 5 to 6 cm of the ascending aorta. The choice of CMR versus CT angiography depends on patient preference, insurance coverage, institutional expertise, and consideration of radiation exposure.

3. In about 20% to 30% of patients with a BAV, other family members also have a BAV and/or an associated aortopathy. A specific genetic cause has not been identified, and the patterns of inheritance are variable. Imaging can identify the presence of a BAV and aortic dilation, but there is a paucity of data on the cost-effectiveness of this approach and whether earlier diagnosis would improve long-term clinical outcomes.

5.1.1.2. Diagnostic Testing: Routine Follow-Up

<table>
<thead>
<tr>
<th>COR</th>
<th>LOE</th>
<th>Recommendations</th>
</tr>
</thead>
<tbody>
<tr>
<td>2a</td>
<td>C-LD</td>
<td>1. In patients with BAV and a diameter of the aortic sinuses or ascending aorta of ≥4.0 cm, lifelong serial evaluation of the size and morphology of the aortic sinuses and ascending aorta by echocardiography, CMR, or CT angiography is reasonable, with the examination interval determined by the degree and rate of progression of aortic dilation and by family history.</td>
</tr>
<tr>
<td>2a</td>
<td>B-NR</td>
<td>2. In patients with a BAV who have undergone AVR, continued lifelong serial imaging of the aorta is reasonable if the diameter of the aortic sinuses or ascending aorta is ≥4.0 cm.</td>
</tr>
</tbody>
</table>

Synopsis

Patients with BAV with and without associated aortic aortopathy require lifelong surveillance. Because progression of valve disease and growth of the aorta can occur in the absence of symptoms, diagnostic imaging plays an integral role in the surveillance process.

Recommendation-Specific Supportive Text

1. Aortopathy is present in approximately 20% to 40% of patients with a BAV and is associated with dilation of the aortic sinuses, the ascending aorta, and/or the arch. In a retrospective case series of 918 patients with BAV followed for 2 to 12 years...
with serial imaging, 47% required valve surgery but only 3.8% required aortic grafting without valve replacement, and <0.1% had aortic dissection.5 In a systematic review of 13 studies with >11,000 patients with a BAV, aortic dilation was present in 20% to 40%, but only 0.4% suffered aortic dissection. Aortic imaging at least annually is prudent in patients with BAV and significant aortic dilation (>4.5 cm) to determine the appropriate timing of surgical intervention. Patients with risk factors that increase the risk of aortic dissection, such as a rapid rate of change in aortic diameter or a family history of aortic dissection, may also require more frequent monitoring. In patients with milder dilation that shows no change on sequential studies and with a negative family history, a longer interval between imaging studies is appropriate.1–4,8,9

2. In a retrospective review of 1286 patients with a BAV who underwent isolated AVR with a median of 12 years of follow-up, subsequent aortic dissection occurred in 1%, ascending aortic replacement surgery was needed in 0.9%, and progressive aortic enlargement was noted in 9.9%.6 In a smaller cohort of 153 patients with a BAV with prior AVR, 3% required proximal aortic surgery after 15 years of follow-up. No cases of aortic dissection were noted.7,10 These studies demonstrate that the aorta may continue to dilate in patients with a BAV who undergo valve replacement surgery.11

5.1.2. Interventions for Patients With BAV

5.1.2.1. Intervention: Replacement of the Aorta

Figure 5. Intervals for imaging the aorta in patients with a BAV.
Colors correspond to Table 2. BAV indicates bicuspid aortic valve; CTA, computed tomographic angiography; CMR, cardiac magnetic resonance; TTE, transthoracic echocardiography.
Synopsis

The timing and type of surgery for replacement of the aorta are dependent on the anatomy of the aorta (as demonstrated on imaging), patient characteristics, and institutional expertise (Figure 6).

Recommendation-Specific Supportive Text

1. Retrospective studies of patients with a BAV have shown that the incidence of aortic dissection is very low and is estimated to be approximately 0.4% with routine surveillance of the aorta. However, data are limited with regard to the degree of aortic dilation at which the risk of dissection is high enough to warrant operative intervention in patients who do not fulfill criteria for AVR on the basis of severe AS or AR. Thus, an individualized approach to the timing of surgical intervention for a dilated aorta is suggested. Surgery is recommended in patients with a BAV with or without symptoms and with a diameter of the aortic sinuses or the ascending aorta of ≥5.5 cm.2

2. Specific risk factors, including family history of aortic dissection, aortic growth rate >0.5 cm per year, and aortic coarctation, are associated with a greater risk of aortic dissection. In patients with these risk factors, operative intervention to replace the aortic sinuses and/or the ascending aorta is reasonable when the aortic dimension is 5.0 to 5.5 cm, if the surgery is performed at a Comprehensive Valve Center.4–7,10–14

3. In patients with a BAV, data are limited with regard to the degree of aortic dilation at which the risk of dissection is high enough to warrant replacement of the ascending aorta at the time of AVR. The risk of progressive aortic dilation and dissection after AVR in patients with BAV has been the subject of several studies, but definitive data are lacking. In patients undergoing AVR because of severe AS or AR, replacement of the ascending aorta is reasonable when the aortic diameter is >4.5 cm.4–7,10–14

4. There are a limited number of patients with BAV who meet criteria for operative intervention on the aortic sinuses and/or ascending aorta but have a well-functioning aortic valve. Because of the growing experience with valve-sparing surgery on highly selected patients,8,9 surgical replacement of the aorta with aortic valve repair or reimplantation may be considered. However, given the complexity of this procedure, surgery should be performed at a Comprehensive Valve Center.

5. Data are limited with regard to the degree of aortic dilation at which the risk of dissection is high enough to warrant operative intervention in patients who do not fulfill criteria for AVR on the basis of severe AS or AR. In asymptomatic patients with a BAV and a diameter of the aortic sinuses and/or ascending aorta of 5.0 to 5.5 cm who are at low surgical risk and have no additional risk factors for aortic dissection, surgery to replace the aortic sinuses and/or ascending aorta may be considered as long as surgery is performed at a Comprehensive Valve Center. Additionally, shared decision-making between the patient and the healthcare team is needed to clearly outline the risks of surgery and weigh them against the potential reduction in future risk of aortic dissection.4–7,10–14

5.1.2.2. Intervention: Repair or Replacement of the Aortic Valve

Synopsis

The indications for the timing of aortic valve intervention in patients with a BAV and AS or AR is similar to those for trileaflet aortic valves. See the respective sections on AS (Section 3.2) and AR (Section 4). The choice of prosthetic valve type in patients with a BAV is similar to that for patients with trileaflet valves. See the section on prosthetic valve choices (Section 3.2.4.1) for full details. Given the unique nature of BAV, however, there are additional specific considerations.
1. Surgical repair of the aortic valve may be feasible in selected patients, depending on valve and aortic root anatomy and tissue characteristics. Published data suggest that valve repair can be performed safely and effectively by surgeons with training and experience in these techniques. However, given the complexities of patient selection and surgical techniques, such surgeries should be performed at a Comprehensive Valve Center.

2. Recent trials have demonstrated the benefits of TAVI in patients with severe, symptomatic AS. However, the early pivotal TAVI trials excluded patients with BAV. Initial studies using early-generation valves suggested a higher rate of paravalvular leak in the BAV population. Data from the STS/ACC Transcatheter Valve Therapies Registry, which includes all consecutive TAVI procedures performed in the United States, suggest that with the use of newer-generation prosthetic valves the rate of paravalvular leak is no different in patients with a BAV than in patients with a trileaflet aortic valve. This registry also showed no difference in mortality rate at 30 days and 1 year between the BAV and tricuspid valve groups. However, the stroke rate at 30 days was higher in the BAV group. Other considerations are the younger age of patients with a BAV, for whom the risk–benefit ratio of TAVI versus SAVR needs careful consideration. RCTs are needed to obtain full clarity on the optimal use of TAVI in this population, as well as long-term outcomes.

6. MITRAL STENOSIS

The incidence of rheumatic MS is low in high-income countries and has been slowly declining in low- and middle-income countries, but MS remains a major cause of valve disease worldwide. Rheumatic MS is much more common in women (about 80% of cases) than in men. The clinical presentation of rheumatic MS varies, with patients from regions with a high disease prevalence presenting at a young age (teen years to age 30 years)
with commissural fusion but pliable noncalcified valve leaflets. In contrast, the presentation in regions with a low disease prevalence occurs more often in older patients (age 50 to 70 years) who present decades after the initial rheumatic fever episode with calcified fibrotic leaflets in addition to commissural fusion and subvalvular involvement. Older patients with MS often have multiple other cardiac and noncardiac comorbidities, such as atherosclerotic disease, hypertension, and diastolic dysfunction, all of which need to be taken into consideration in patient evaluation and management.1,2

Although most of MS in the world results from rheumatic heart disease, nonrheumatic calcific MS is found with increasing frequency in the elderly population in high-income countries Calcific MS is the result of calcification of the mitral annulus that extends into the leaflet bases, resulting in both narrowing of the annulus and rigidity of the leaflets.3–5

### 6.1. Stages of MS

The stages of MS are defined by patient symptoms, valve anatomy, valve hemodynamics, and the consequences of valve obstruction on the left atrium (LA) and pulmonary circulation (Table 16). Rheumatic valve disease is the primary cause of MS, with anatomic features reflecting this disease process. Hemodynamic severity is best characterized by valve area, either directly planimetered by 2D or 3D imaging or calculated from the diastolic pressure half-time.1 The definition of “severe” MS is based on the severity of symptoms, as well as the severity at which intervention will improve symptoms. Thus, a mitral valve area ≤1.5 cm² is considered severe, which typically corresponds to a transmirtal mean gradient of >5 mm Hg to 10 mm Hg at a normal heart rate. However, mean pressure gradient is highly dependent on transvalvular flow rate, the diastolic filling period, and heart rate. Mitral pressure half-time also has limitations, and is dependent upon LV and LA compliance as well as stenosis severity. Other approaches to calculation of the mitral valve area, such as the continuity equation or Gorlin formula, may be used if discrepancies exist. These pertain primarily to patients with rheumatic MS.

### Synopsis

For patients with rheumatic MS, TTE is the initial diagnostic test to determine the severity of the stenosis.
and suitability for PMBC. If PMBC is being considered, a TEE can further evaluate the presence and severity of concomitant MR and rule out LA thrombus.

**Recommendation-Specific Supportive Text**

1. TTE is the imaging modality of choice to elucidate the anatomy and functional significance of rheumatic MS.\(^1\) The parasternal long-axis window can identify the characteristic diastolic doming of the mitral valve, whereas short-axis scanning will demonstrate commissural fusion and allow planimetry of the mitral orifice. Use of 3D echocardiography (either TTE or TEE) provides greater accuracy of measurement of the mitral valve area.\(^7,8\) Doppler echocardiography mean transvalvular gradients always should be reported with heart rate because a high heart rate will result in overestimation of stenosis severity.\(^9\) Estimated RV systolic pressure is obtained from the TR velocity. Concomitant MR should be quantified, along with any other valve lesions (Section 7.3.1.1). Several scores are available for evaluation of mitral valve morphology and prediction of outcomes with PMBC, and these scores consider valve thickening, mobility, and calcification with subvalvular chordal fusion.\(^10,11\) Characterization of commissural morphology and calcification further predicts suitability for commissurotomy.\(^2,3,12,13\)

Additional assessment of rheumatic MS includes the mitral pressure half-time, with acknowledgment that this parameter is also affected by LA and LV compliance. If the mean gradient does not match the valve area, other methods, such as the continuity equation, should be considered.\(^14\)

2. TEE offers excellent visualization of the mitral valve and LA and is an alternative approach to assessment of rheumatic MS in patients whose TTE images are technically limited. In patients being considered for PMBC, a TEE can rule out LA cavity and appendage thrombi.\(^4,6\) TEE also is useful for evaluation of MR severity in patients being considered for PMBC because shadowing of the LA on TTE may result in underestimation of MR severity. MR that is more than mild is a contraindication to PMBC.

**6.2.1.2. Diagnostic Testing: Changing Signs or Symptoms**

Patients with an established diagnosis of rheumatic MS may experience a change in symptoms attributable to disease progression related to recurrent episodes of rheumatic fever leading to further valve damage; progressive narrowing of the mitral valve attributable to leaflet fibrosis and thickening; progressive pulmonary hypertension; or worsening of concomitant MR or other valve lesions. In addition, symptom status may change with no change in rheumatic MS severity because of an increased hemodynamic load (for example, because of pregnancy), new-onset or rapid AF, fever, anemia, or hyperthyroidism, or hemodynamic shifts in the perioperative period of patients undergoing noncardiac surgery. In such cases, a repeat TTE examination can quantify the mitral valve gradient and area, as well as other parameters that may contribute to a change in symptoms.

**6.2.1.3. Diagnostic Testing: Routine Follow-Up**

Rheumatic MS is a slowly progressive disease, characterized by a prolonged latent phase between the initial rheumatic illness and the development of valve stenosis.\(^1,3\) The latent phase is an interval typically measured in decades in high-income countries but in considerably shorter periods in low- to middle-income countries, likely because of recurrent carditis. Once mild stenosis has developed, further narrowing is slow (decrease in valve area of 0.1 cm² per year on average), although the rate of progression is highly variable.\(^3\) Importantly, progressive enlargement of the RV and a rise in RV systolic pressure can be observed, even in the absence of a decrease in mitral valve area. Accordingly, repeat TTE at intervals dictated by valve area is an important aspect of disease management, even in patients without symptoms (Table 4).

**6.2.1.4. Diagnostic Testing: Cardiac Catheterization**

In the contemporary era, assessment of MS and associated lesions can be obtained in most patients by TTE, occasionally supplemented by TEE. However, there will be a subset of patients with nondiagnostic studies or for whom there is discordance between the clinical and echocardiographic findings. In older patients, other factors contributing to symptoms may need to be further sorted out, such as concomitant diastolic dysfunction, LA noncompliance, or intrinsic pulmonary vascular disease. Cardiac catheterization is useful in these patients to further characterize rheumatic MS hemodynamics and etiology of symptoms, as it can measure absolute pressures in the LV, LA, and pulmonary circulation at rest and with exercise. Although the mean pulmonary artery wedge pressure is an acceptable substitute for mean LA pressure, the LV–to–pulmonary wedge gradient will overestimate the true transmitral gradient because of phase delay and delayed transmission of pressure changes.\(^1\) Nonetheless, the absolute mean pulmonary artery wedge pressure and its relationship to the LV diastolic pressure and pulmonary artery pressure can provide useful clinical information. The Gorlin equation can be used for an independent calculation of mitral valve area.\(^2,3\)
### Synopsis

Exercise testing with either Doppler echocardiography or cardiac catheterization is important when the resting hemodynamics do not match the clinical symptoms in patients with rheumatic MS.

#### Recommendation-Specific Supportive Text

1. Exercise testing with hemodynamics is helpful in the management of rheumatic MS when a patient's symptoms seem significantly greater than or less than would be expected from TTE. Results have been published in which both exercise and dobutamine were used with Doppler echocardiography, although exercise is preferred in general as the more physiological test. Over the years, experience with treadmill exercise, with images and Doppler obtained immediately after stress, but bicycle exercise allows data acquisition at various stages of exercise. Bicycle exercise testing during cardiac catheterization can also be performed for direct measurements of pulmonary artery wedge pressure and pulmonary pressures at rest and with exercise. Simple functional capacity helps to quantify the patient's symptoms. Changes in valve gradient should be measured, as well as the estimated pulmonary artery systolic pressure. If the patient cannot exercise, increasing the heart rate with maneuvers such as leg lifts or sit-ups may be useful.

### 6.2.2. Medical Therapy

#### Recommendations for Medical Therapy in Patients With Rheumatic MS

**Synopsis**

In patients with rheumatic MS and AF, anticoagulation decreases the incidence of thromboembolic events. Anticoagulation can also decrease the incidence of thromboembolic events in patients with rheumatic MS if there has been a prior embolic event or if an LA thrombus was visualized. In symptomatic patients with MS who are in normal sinus rhythm and have tachycardia, heart rate control with beta blockers, calcium channel blockers, or ivabradine will lengthen the diastolic filling period and lower LA pressure. However, routine use of heart rate control for patients with rheumatic MS in normal sinus rhythm in the absence of tachycardia may result in chronotropic incompetence, preventing an adequate cardiac output response to exercise.
for rate control versus rhythm control is dependent on multiple factors, including the duration of AF, hemodynamic response to AF, LA size, prior episodes of AF, and history of embolic events. It is more difficult to achieve rhythm control in patients with rheumatic MS because the rheumatic process itself may lead to progressive fibrosis and enlargement of the atria, fibrosis of the internodal and interatrial tracts, and damage to the sinoatrial node.

3. The use of negative dromotropic agents for the treatment of symptoms in patients with rheumatic MS in normal sinus rhythm has been controversial. Although a reduction in heart rate and prolongation of the diastolic filling period will decrease the transmirtal mean gradient, studies have shown that treatment with beta blockade may not improve or may even decrease exercise tolerance, most likely because of the limitation of the cardiac output attributable to a limited stroke volume and chronotropic incompetence.9–11 Nonetheless, there are now several randomized trials that have examined beta blockers and ivabradine in patients with rheumatic MS and have shown that either drug can increase exercise duration and improve symptoms.2–15 To explain these differences, the earlier trials that found no benefit of beta blockers were performed in older patients with underlying chronotropic incompetence, whereas the randomized trials showing benefit were performed primarily in younger patients with higher resting and exercise-induced heart rates. Thus, the use of beta blockers or ivabradine to improve symptoms may be effective only in patients who do not have underlying chronotropic incompetence. When medical therapy is considered for relief of symptoms in patients with rheumatic MS, it must be remembered that intervention with PMBC relieves symptoms in those patients with an appropriate valve morphology.

6.2.3. Intervention

| Recommendations for Intervention for Rheumatic MS (Continued) |
|-------------------|-----------------|----------------|
| COR | LOE | Recommendations |
| 2a | B-NR | 3. In asymptomatic patients with severe rheumatic MS (mitral valve area ≤1.5 cm², Stage C) and favorable valve morphology with less than 2+ MR in the absence of LA thrombus who have elevated pulmonary pressures (pulmonary artery systolic pressure >50 mmHg), PMBC is reasonable if it can be performed at a Comprehensive Valve Center.14 |
| 2b | C-LD | 4. In asymptomatic patients with severe rheumatic MS (mitral valve area ≤1.5 cm², Stage C) and favorable valve morphology with less than 2+ MR in the absence of LA thrombus who have new onset of AF, PMBC may be considered if it can be performed at a Comprehensive Valve Center.15 |
| 2b | C-LD | 5. In symptomatic patients (NYHA class II, III, or IV) with rheumatic MS and an mitral valve area >1.5 cm², if there is evidence of hemodynamically significant rheumatic MS on the basis of a pulmonary artery wedge pressure >25 mmHg or a mean mitral valve gradient >15 mmHg during exercise, PMBC may be considered if it can be performed at a Comprehensive Valve Center.16 |
| 2b | B-NR | 6. In severely symptomatic patients (NYHA class III or IV) with severe rheumatic MS (mitral valve area ≤1.5 cm², Stage D) who have a suboptimal valve anatomy and who are not candidates for surgery or are at high risk for surgery, PMBC may be considered if it can be performed at a Comprehensive Valve Center.17–19 |

*2+ on a 0 to 4+ scale according to Sellar’s criteria or less than moderate by Doppler echocardiography.20

Synopsis

The optimal treatment of patients with rheumatic MS is either PMBC or surgery (open or closed commissurotomy). Although these procedures can result in excellent outcomes by splitting open fused commissures to relieve stenosis, both the catheter-based and the surgical procedures require a high level of expertise and should be performed at experienced centers. In the United States, there has been a 7.5% decrease in the use of PMBC, accompanied by a 15.9% increase in complication rate.21 Excellent short- and long-term outcomes can be achieved with surgical commissurotomy, but surgical commissurotomy is not routinely or widely performed by most surgeons in the United States. Thus, in the clinical decision-making process for a patient with rheumatic MS, it is essential to know the results of the available interventional procedures. Mitral valve replacement is an option for treatment only if there is no other option and the patient has severe limiting symptoms (Figure 7).

Recommendation-Specific Supportive Text

1. Randomized trials have established the safety and efficacy of PMBC as compared with surgical closed or open commissurotomy in patients with a...
favorable valve morphology with less than 2+ MR in the absence of LA thrombus. PMBC is performed by advancing one or more balloon catheters across the mitral valve and inflating them, thereby splitting the commissures. Favorable valve morphology consists of mobile and relatively thin valve leaflets, which are free of calcium, in the absence of significant subvalvular fusion. An anatomic mitral morphology score can be used to determine suitability for PMBC and to evaluate the appearance of the commissures and degree of calcification. Clinical factors, such as age, NYHA class, and presence or absence of AF, are also predictive of outcome. Older patients with lower gradients (<10 mm Hg) will not have as good an outcome as patients with higher gradients, probably because of other concomitant problems that cause symptoms, such as LV diastolic dysfunction and LA noncompliance, measured by net atrial-ventricular compliance.

PMBC should be performed only by experienced operators, with immediate availability of surgical backup for potential complications. Long-term follow-up has shown 70% to 80% of patients with an initial good result after PMBC to be free of recurrent symptoms at 10 years, and 30% to 40% are free of recurrent symptoms at 20 years.2-7

2. Mitral valve surgery is an established therapy for rheumatic MS, with the preferred approach being commissurotomy (either closed, where the valve is opened blindly through the LA or LV, or open, which allows more extensive surgery under direct visualization) when anatomy is favorable.31-36 However, in the presence of severe valvular thickening and subvalvular fibrosis with leaflet tethering, mitral valve replacement may be the best option. In addition to those who have suboptimal valve anatomy (or failed PMBC), patients with moderate or severe TR may also have a better outcome with a surgical approach that includes tricuspid valve repair.37 Patients undergoing surgical commissurotomy at centers with a high level of expertise may have better long-term outcomes than those undergoing PMBC.6,7 Because the natural history of rheumatic MS is one of slow progression over decades, surgery should be delayed until the patient has severe limiting symptoms (NYHA class III or IV), particularly if mitral valve repair is contemplated.

3. Although most patients with rheumatic MS who are asymptomatic will do well for years without intervention, an elevation of pulmonary artery pressure is an indication that there is progressive elevation of LA pressure affecting the pulmonary circulation. An elevated pulmonary pressure can be assessed by Doppler echocardiography. Although there may be a decrease in pulmonary pressure after relief of the rheumatic MS, some patients will have developed intrinsic pulmonary vascular disease, as evidenced by a poorer long-term survival rate in patients who have pulmonary hypertension before...
intervention. An elevated pulmonary arterial resistance before intervention is associated with RV dysfunction and TR after the procedure. Thus, PMBC may prevent the adverse consequences of irreversible pulmonary hypertension if it can be performed with a high success rate and low risk in patients who are developing pulmonary hypertension. Correction of the MR before irreversible changes occur can be curative. Thus, in chronic primary MR, MR is the disease.

4. The new onset of AF may be an indication for proceeding with PMBC in the asymptomatic patient with a favorable valve morphology for several reasons. First, AF may be the equivalent of symptom onset, signifying that rheumatic MS is resulting in progressive LA damage. Second, AF increases the risk of thromboembolic events in patients with rheumatic MS. In addition, a shortened diastolic filling interval with AF and a rapid ventricular response further increase LV pressure. Finally, the presence of AF is associated with worse outcomes in patients with rheumatic MS and with suboptimal results after PMBC.

5. Some patients have symptoms from rheumatic MS even with a mitral valve area >1.5 cm² and a resting mean transmitral gradient <10 mm Hg. This may be related to the variability and reliability of measuring a mitral valve area by either planimetrying a short-axis image of the mitral valve or using a diastolic half-time for indirect calculation of the mitral valve area. There are also patients who have a relatively low gradient at rest who generate a much higher gradient with exercise, with symptoms developing from the higher LA pressure. Thus, in these patients in whom there is a discrepancy between the clinical symptoms and the resting hemodynamics, exercise testing with measurement of the mean transmitral gradient or the direct pulmonary artery wedge, or both, is useful. Patients who increase their gradients to >15 mm Hg with exercise have been shown to improve symptomatically after PMBC.

6. Both anatomic valve morphology and the presence of commissural calcification predict successful PMBC. However, in all such series, this predictive ability is not absolute, with 42% of patients with an anatomic valve Wilkins morphology score >8 having an optimal outcome (25% increase in mitral valve area to >1.5 cm²) and 38% of patients with commissural calcium having event-free survival at 1.8 years. Accordingly, severely symptomatic patients who are poor surgical candidates may benefit from PMBC even with suboptimal valve anatomy. Patients who refuse surgery may also be offered PMBC after discussion about the potential complications associated with this procedure when it is performed in patients with suboptimal valve anatomy.

### 6.3. Nonrheumatic Calcific MS

#### Recommendation for Nonrheumatic Calcific MS

<td>1. In severely symptomatic patients (NYHA class III or IV) with severe MS (mitral valve area ≤1.5 cm²; Stage D) attributable to extensive mitral annular calcification, valve intervention may be considered only after discussion of the high procedural risk and the individual patient’s preferences and values.1–3</td>
</tr>
</tbody>
</table>

#### Synopsis

Although most MS in the world results from rheumatic heart disease, calcific MS is found with increasing frequency in the elderly population in high-income countries. Calcific MS is the result of calcification of the mitral annulus that extends into the leaflet bases, resulting both in narrowing of the annulus and rigidity of the leaflets. In contrast to rheumatic MS, there is no commissural fusion, and the leaflet tips are usually unaffected. The progression of calcific MS is variable, ranging from an increase of <1.0 to up to 9 mm Hg per year. The prognosis of this group of patients is poor, with a 5-year survival rate <50%, most likely because of advanced age and other comorbidities. Determination of the severity of stenosis is difficult because of extensive calcification, which prevents measurement of an accurate planimetered area, and the significant abnormalities of LA and LV compliance, which cause a high gradient in the absence of severe obstruction. These patients are at high risk with any intervention because of the extensive calcification, as well as advanced age and multiple comorbidities. Thus, in patients with calcific MS, the indications for any intervention differ from those for rheumatic MS, and intervention for calcific MS should be performed only in the highly symptomatic patient. Nonrheumatic MS can also be present after radiation therapy and after a mitral valve repair with a small annuloplasty ring.

#### Recommendation-Specific Supportive Text

1. Indications for intervention in patients with calcific MS are different from those for rheumatic MS for the following reasons. First, because calcification involves the annulus and base of the leaflets without commissural fusion, there is no role...
for PMBC or surgical commissurotomy. Second, the presence of severe mitral annular calcification can be quite challenging for the surgeon because of technically difficult in securely attaching the prosthetic valve and placement of the prosthetic valve may result in narrowing of the orifice.17–22 Finally, patients with calcification are often elderly and debilitated, have multiple comorbidities, and are at high surgical risk.1–3 For these reasons, intervention should be delayed until symptoms are severely limiting and cannot be managed with diuresis and heart rate control. Catheter-based therapies for these high–surgical risk patients are being developed and evaluated.23

7. MITRAL REGURGITATION

7.1. Acute MR

Acute MR may be caused by disruption of different parts of the mitral valve apparatus. IE may cause leaflet perforation or chordal rupture. Spontaneous chordal rupture may occur in patients with myxomatous mitral valve disease. Rupture of the papillary muscle occurs in patients who have an acute ST-segment–elevation myocardial infarction, usually associated with an inferior infarction. The acute volume overload on the LV and LA results in pulmonary congestion and low forward cardiac output.1–4 Diagnosis of the presence and etiology of acute MR, along with urgent intervention, may be lifesaving.

7.1.1. Diagnosis of Acute MR

In patients with acute MR, TTE is the initial imaging modality of choice to evaluate LV function, RV function, pulmonary artery pressure, and mechanism of MR. The patient with severe acute MR, which might occur from chordal rupture, usually experiences acute hemodynamic decompensation. The sudden volume overload increases LA and pulmonary venous pressures, leading to pulmonary congestion and hypoxia, whereas decreased blood delivery to the tissues with a concomitant decrease in LV systolic pressure limits the pressure gradient, driving MR to early systole. Thus, the murmur may be short and unimpressive, as may be the color jet of MR by TTE. In the presence of sudden acute and hemodynamic instability after myocardial infarction, with hyperdynamic LV function by TTE and no other cause for the deterioration, TEE can be especially helpful in detecting papillary muscle or chordal rupture or valvular vegetations and annular abscesses that may further accentuate the need for a more urgent surgical approach.1

7.1.2. Medical Therapy

Vasodilator therapy improves hemodynamic compensation in acute MR. The premise for use of vasodilators in acute MR is a reduction in impedance of aortic flow, thereby preferentially guiding flow away from the LV-to-LA pathway, decreasing MR while simultaneously increasing forward output to the LV-to-aortic pathway.1–2 This is usually accomplished by infusion of an easily titratable agent, such as sodium nitroprusside or nicardipine. Use of vasodilators is often limited by systemic hypotension that is exacerbated when peripheral resistance is decreased. Intra-aortic balloon counterpulsation can be helpful to treat acute severe MR. By lowering systolic aortic pressure, intra-aortic balloon counterpulsation decreases LV afterload, increasing forward output while decreasing regurgitant volume. Simultaneously, intra-aortic balloon counterpulsation increases diastolic and mean aortic pressures, thereby supporting the systemic circulation. The use of a percutaneous circulatory assist device may stabilize a patient with acute hemodynamic compromise before the procedure.

7.1.3. Intervention

Prompt mitral valve surgery, preferably mitral repair if possible, is lifesaving in the symptomatic patient with acute severe primary MR. The severity of acute primary MR is variable, and some patients with more moderate amounts of MR may develop compensation as LV dilatation allows for lower filling pressure and increased forward cardiac output. However, most patients with acute severe MR require surgical correction for reestablishment of normal hemodynamics and for relief of symptoms.1–5 This is especially true for a complete papillary muscle rupture that causes very severe MR, which is poorly tolerated.

7.2. Chronic Primary MR

7.2.1. Stages of Chronic Primary MR

In assessing the patient with chronic MR, it is important to distinguish between chronic primary (degenerative) MR and chronic secondary (functional) MR, as these 2 conditions have more differences than similarities. Primary MR is a disease of the mitral valve apparatus, and secondary MR is a disease of the ventricle or atria. In chronic primary MR, the pathology of ≥1 of the components of the valve (leaflet, chordae tendineae, papillary muscles, annulus) causes valve incompetence, with systolic regurgitation of blood from the LV to the LA (Table 17). The most common cause of chronic primary MR in high-income countries is mitral valve prolapse, which has a wide spectrum of etiology and presentation. Younger populations present with severe myxomatous degeneration with gross redundancy of both anterior and posterior leaflets and the chordal apparatus (Barlow’s valve). A subset of these patients will present with ventricular arrhythmias, mitral annular disjunction, and LV dilation. Alternatively, older populations present with fibroelastic deficiency disease, in which lack of connective tissue leads to chordal rupture. The differentiation between these 2 etiologies may have implications for operative intervention. Other
Recommendation-Specific Supportive Text

1. TTE images provide the diagnostic data needed for clinical decision-making in chronic primary MR. The outcome of the patient with chronic primary MR is determined by lesion severity, symptom status, the presence of LV dysfunction, and whether valve pathology is correctable by valve repair, which is superior to valve replacement when repair is possible. Usually only severe (not mild or moderate) MR leads to negative sequelae. Favorable loading conditions in MR increase LVEF but do not affect the extent of shortening. Thus, a “normal” LVEF in MR is approximately 70%. The onset of LV dysfunction is inferred when LVEF declines toward 60% or when the LV is unable to contract to a diameter <40 mm at end systole. Although chamber volumes may give more information about cardiac remodeling, 2D volume accuracy is variable in clinical practice. Determination of MR severity is made by integrating all available data. These data include measurements of the effective orifice area, regurgitant volume, regurgitant fraction (obtained by using the proximal isovelocity surface area or quantitative Doppler flow measurements), color jet area, vena contracta, continuous-wave Doppler intensity, and the trans-mitral jet velocity curve. In mitral valve prolapse, MR may be non-holosystolic (mid-late systole). Thus, careful attention in assessing its severity is needed. It is conventional to overestimate its severity on a single image frame. Volumetric measurements provide a better assessment in this situation.

2. TEE provides excellent imaging of the mitral valve and should be performed when TTE images are inadequate to fulfill the goals of TTE noted previously. TEE is especially useful in cases of MR attributable to IE because TEE can provide information about other potentially infected structures. TEE may allow more precise quantitation of regurgitant severity and provide a better estimate of the likelihood of a successful surgical valve repair than does TTE. Three-dimensional TEE may be helpful in further visualizing the abnormal mitral valve anatomy, offering a “surgical” view of the valve. Mitral valve repair is preferable to valve replacement because of a lower operative mortality rate and avoidance of the complications inherent to prosthetic valves. Although the final decision about repair versus replacement is made in the operating room, TEE can help predict surgical strategy beforehand. Thus, if repair is likely, it might be performed earlier in the course of the disease than if replacement is necessary.

3. In most cases, TTE provides the data needed for adequate cardiac evaluation of the patient with MR. However, in cases where TTE image quality is poor, CMR may be of value in MR evaluation. CMR produces highly accurate data on LV volumes, RV volumes, and LVEF, as well as an assessment of regurgitant fraction for estimating MR severity. However, outcome data on large numbers of patients have been derived from echocardiographic, and it is uncertain whether CMR data can be used interchangeably with echocardiographic data in predicting outcomes. CMR is less helpful in establishing mitral pathoanatomy.
4. Intraoperative TEE is the standard for imaging during MR surgery. Before the operative incision, TEE may give the surgeon a better understanding of the valve anatomy and type of repair that will likely be performed, although this decision is ultimately made when the valve is inspected visually.10,11 Three-dimensional TEE (“surgical view”) may be helpful in further visualizing the abnormal mitral valve anatomy. Because anesthesia lessens afterload, preload, and mitral valve closing force, decisions about severity of MR should be evaluated at the same loading conditions as occurred during the awake state. Intraoperative TEE is especially helpful in gauging the adequacy of repair.11 Because even mild residual MR after repair increases the likelihood of later repair failure that would necessitate reoperation,21 surgeons strive for near-perfect operative repair. Adequacy of repair is judged by TEE after physiological filling pressure and blood pressure have been established. If more than trivial MR is detected in the operating room after repair, repair revision usually ensues. TEE also helps to diagnose underfilling of the LV, which can lead to systolic anterior leaflet motion with outflow obstruction and unneeded repair. In those patients with primary severe MR who are at high surgical risk, TEE is helpful in determining the feasibility of transcatheter edge-to-edge repair.22,23

<td>B-NR</td>
<td>1. In patients with primary MR (Stages B to D) and new-onset or changing symptoms, TTE is indicated to evaluate the mitral valve apparatus and LV function.12</td>
</tr>
</tbody>
</table>

Synopsis

A repeat TTE provides clinically relevant information about patients who are being followed for primary MR who develop new-onset symptoms.
Recommendation-Specific Supportive Text

1. The onset of symptoms in severe MR (dyspnea on exertion, orthopnea, or declining exercise tolerance) is an indication for mitral intervention even if LV function is preserved. Symptoms are the culmination of the pathophysiology of MR and may indicate changes in LV or LA compliance; increase in pulmonary artery pressure; decrease in RV function; or the coexistence of TR. Therefore, symptoms add pathophysiological data not readily available from imaging, if other confounding factors can be excluded. Furthermore, there is no evidence that treatment with diuretics or other therapies that might relieve symptoms changes the prognostic effect of symptom onset. Once symptoms have occurred and are caused by MR, mitral valve surgery will improve the natural history even if medication has led to improvement. Repeat TTE at the time of symptom onset is indicated to confirm that symptoms are likely attributable to MR or its effect on the LV, which in turn supports surgical correction. The new onset of AF is also an indication for repeat TTE to look for changes in severity of MR and the status of the LV.

7.2.2.3. Diagnostic Testing: Routine Follow-Up

<td>2. In asymptomatic patients with severe primary MR (Stages B and C1), use of serum biomarkers and novel measurements of LV function, such as global longitudinal strain, may be considered as an adjunct to guide timing of intervention.</td>
<td></td>
</tr>
</tbody>
</table>

Synopsis

Asymptomatic patients with severe primary MR require periodic TTE to determine optimal timing of intervention. Biomarkers and other measures of LV function, such as global longitudinal strain, may also be helpful to guide intervention.

Recommendation-Specific Supportive Text

1. TTE provides valuable information for surveillance of LV function (estimated by LVEF and LVESD) and pulmonary artery pressure in asymptomatic patients with severe primary MR (Stage C1) if performed every 6 to 12 months. Chronic severe MR is tolerated poorly, reaching a trigger for surgery at an average rate of about 8% per year. This progression varies from patient to patient, and because prognosis worsens if correction of MR is delayed beyond the onset of these triggers, referral to a Comprehensive Valve Center for early repair or careful surveillance is of value. Because echocardiographic measurements are variable, management decisions that rest on these measurements should be confirmed by repeat sequential TTE. In patients with milder chronic primary MR (Stages A and B), TTE is indicated periodically to evaluate for changes in MR severity, depending on valve anatomy and other considerations, because regurgitation may worsen over time. Because this process may develop slowly, MR can become severe and even lead to LV dysfunction in the absence of symptoms or clinical signs (Table 4).

2. Symptom onset is a crucial demarcation point in the natural history of MR and also a trigger for intervention. Because symptoms develop gradually, patients may fail to recognize or ignore symptoms. Natriuretic peptide levels provide objective evidence in patients with chronic severe MR, with elevated levels indicating increased reliance on preload to maintain an adequate forward cardiac output. Thus, serum natriuretic peptide levels may be helpful in making management decisions about intervention when other data are conflicting. LVEF is used as a key determinant of LV function in timing MR intervention. Unfortunately, LVEF is load dependent and often overestimates LV function in MR. Global longitudinal strain, although also load dependent, appears more sensitive to LV dysfunction in patients with chronic MR and, as such, might give warning that LV function is declining before LVEF becomes abnormal. Thus, novel markers of LV systolic function, such as global longitudinal strain, may be useful adjuncts in assessing LV function in patients with chronic MR.

7.2.2.4. Diagnostic Testing: Cardiac Catheterization

Left ventriculography and hemodynamic measurements are useful when clinical assessment and noninvasive tests are inconclusive or discordant with regard to 1) severity of MR, 2) LV function, or 3) the need for surgery. Noninvasive imaging is adequate for evaluation of MR in most cases. However, invasive hemodynamic evaluation may be necessary in some cases, especially when there is a clinical discrepancy between symptomatic status and noninvasive testing. Elevated filling pressures support a cardiac cause of dyspnea and may indicate severely abnormal pathophysiology even when the patient claims to be asymptomatic. Conversely, a normal invasive hemodynamic examination in a symptomatic
patient with what appears to be less than severe MR suggests a noncardiac cause for the symptoms. Hemodynamic evaluation can be especially helpful in patients with concomitant lung disease. Normal LA (or pulmonary artery wedge) pressure and a large transpulmonary gradient suggest pulmonary hypertension that is attributable to lung disease rather than mitral valve disease. Left ventriculography may also be of diagnostic benefit. Whereas echocardiographic-Doppler interrogation of the mitral valve measures flow velocity, ventriculography uses the density of contrast to determine the amount of blood flow from the LV to the LA. Although only semi-quantitative, a carefully performed ventriculogram can help in quantifying MR severity. Additional hemodynamic interventions, such as exercise or leg raising, may be helpful when the resting information is equivocal.

7.2.2.5. Diagnostic Testing: Exercise Testing

**Recommendation for Diagnostic Testing: Exercise Testing for Chronic Primary MR**

Referenced studies that support the recommendation are summarized in Online Data Supplement 28.

<table>
<thead>
<tr>
<th>COR</th>
<th>LOE</th>
<th>Recommendation</th>
</tr>
</thead>
<tbody>
<tr>
<td>2a</td>
<td>B-NR</td>
<td>1. In patients with primary MR (Stages B and C) and symptoms that might be attributable to MR, hemodynamic exercise testing using Doppler echocardiography or cardiac catheterization or cardiopulmonary exercise testing is reasonable.</td>
</tr>
</tbody>
</table>

**Synopsis**

In a subset of apparently asymptomatic patients with severe primary MR, exercise testing with hemodynamics can provide additional diagnostic and prognostic information.

**Recommendation-Specific Supportive Text**

1. The onset of symptoms represents a key development in severe MR. However, some patients may not recognize their symptoms, may deny them, or may alter their lifestyle to remain asymptomatic. A formal treadmill exercise test can establish true exercise tolerance and can also form the baseline for future symptom assessment. Additional information about a cardiac or noncardiac limitation can be obtained from oxygen consumption measurements during exercise. When patients do complain of symptoms, they usually complain of dyspnea with exertion, yet noninvasive evaluation is usually made at rest. Exercise echocardiography or exercise invasive hemodynamics may add additional prognostic value beyond conventional exercise treadmill testing in patients with asymptomatic moderate or severe chronic primary MR.\(^1\) MR may worsen during exercise, or filling pressures may become markedly abnormal, helping to demonstrate MR as the cause of the patient’s dyspnea.\(^1\)

### 7.2.3. Medical Therapy

**Recommendations for Medical Therapy for Chronic Primary MR**

Referenced studies that support the recommendations are summarized in Online Data Supplement 29.

<table>
<thead>
<tr>
<th>COR</th>
<th>LOE</th>
<th>Recommendations</th>
</tr>
</thead>
<tbody>
<tr>
<td>2a</td>
<td>B-NR</td>
<td>1. In symptomatic or asymptomatic patients with severe primary MR and LV systolic dysfunction (Stages C2 and D) in whom surgery is not possible or must be delayed, GDMT for systolic dysfunction is reasonable.(^1)</td>
</tr>
<tr>
<td>3: No Benefit</td>
<td>B-NR</td>
<td>2. In asymptomatic patients with primary MR and normal LV systolic function (Stages B and C1), vasodilator therapy is not indicated if the patient is normotensive.(^2)</td>
</tr>
</tbody>
</table>

**Synopsis**

In patients with primary MR, there is no convincing evidence that vasodilator therapy reduces MR severity. However, GDMT for LV systolic dysfunction or systemic hypertension should be implemented as in any patient with these conditions.

**Recommendation-Specific Supportive Text**

1. Patients with MR and LV dysfunction experience myocardial damage and HF. With onset of LV systolic dysfunction, surgery is usually indicated. However, in those patients in whom surgery (or transcatheter repair) is not performed or will be delayed, medical therapy for systolic dysfunction may be helpful to treat the LV dysfunction alone. Although data specific to patients with MR with LV dysfunction are sparse, treatment of such patients would consist of the standard regimen for HF, including beta-adrenergic blockade, ACE inhibitors or ARBs, and possibly aldosterone antagonists.\(^1\)\(^-\)\(^3\) Perhaps the best data exist for the use of beta blockers,\(^1\) which reverse LV dysfunction in experimental MR.\(^2\) Patients who are receiving beta blockers may have better surgical outcomes and delayed onset of LV dysfunction as compared with those not taking these medications.\(^3\) ACE inhibition has not been effective in experimental MR with LV dysfunction. Because aldosterone antagonism is thought to work in part by inhibiting fibrosis, its role in MR, where little fibrosis occurs, is unclear.

2. Because vasodilator therapy appears to be effective in acute severe symptomatic MR, it seems reasonable to attempt afterload reduction in chronic asymptomatic MR with normal LV function in an effort to forestall the need for surgery. However, the results from the limited number of trials addressing this therapy have been disappointing, demonstrating little or no clinically important benefit.\(^4\)\(^-\)\(^8\) Conversely, because vasodilators decrease LV size and mitral closing force, they may increase...
mitral valve prolapse, worsening rather than decreasing severity of MR. The foregoing does not apply to patients with concomitant hypertension. Hypertension must be treated because of the well-known morbidity and mortality associated with that condition and because increased LV systolic pressure by itself increases the systolic transmitral gradient and worsens severity of MR.

7.2.4. Intervention

Recommendations for Intervention for Chronic Primary MR

<tr>
<td>2b</td>
<td>B-NR</td>
<td>8. In patients with severe primary MR where leaflet pathology is limited to less than one half the posterior leaflet, mitral valve replacement should not be performed unless mitral valve repair has been attempted at a Primary or Comprehensive Valve Center and was unsuccessful.11,14,20–22</td>
</tr>
</tbody>
</table>

Synopsis

Anterior and/or bileaflet primary mitral valve disease requires a complex and extensive repair20,23–26 and durability of the repair is less certain than for simple posterior leaflet intervention. Freedom from reoperation is approximately 80%, and freedom from recurrent moderate or severe MR is 60% at 15 to 20 years in complex cases. These results are superior to the results of mitral valve replacement if the repair is performed at high-volume valve surgery centers,27–29 even in elderly patients.30,31 Repair should also be attempted, if possible, with other causes of severe MR, such as papillary muscle rupture, IE, and cleft mitral valve. However, the results of very complex repair in younger patients may be matched by the results of durable mechanical mitral valve replacement with careful management of anticoagulation. The Heart Valve Team should assign complex repairs to experienced mitral valve surgeons with established excellent operative and long-term outcomes. The probability of mitral valve repair rather than mitral valve replacement and overall outcome correlate with surgeon-specific mitral volumes.21,27 The hospital mortality rate is 50% lower, on average, in the highest-volume hospitals that perform 50 repairs per year. However, some low-volume hospitals outperform the median high-volume hospitals. This overlap suggests that hospital–or surgeon-specific volumes should not be used as a surrogate for actual surgeon-specific repair rates and outcomes (Figure 8). The management of patients with combined severe primary MR and AS is discussed in the Mixed Valve Disease section (Section 10.2.2).

Recommendation-Specific Supportive Text

1. Primary MR is a mechanical problem of the leaflet coaptation that has only a mechanical solution—that of mitral valve mechanical intervention. The onset of symptoms that results from severe MR worsens prognosis even when LV function appears to be normal.1,2 and the negative prognosis extends even to mild symptoms.2 Thus, the onset of symptoms is an indication for prompt mitral valve surgery.

2. The goal of therapy in MR is to correct it before the onset of LV systolic dysfunction and its subsequent adverse effect on patient outcomes. The ideal time for mitral valve surgery is when the patient’s LV approaches but has not yet reached the parameters that indicate systolic dysfunction (LVEF ≤60% or LVESD ≥40 mm).3–7,16 Because symptoms do not always coincide with LV dysfunction, imaging surveillance is used to plan surgery before severe dysfunction has occurred. If moderate LV dysfunction is already present, prognosis is worse after mitral valve operation.5–7,9,15,16 Thus, further delay (although symptoms are absent) will lead to greater LV dysfunction and a
still worse prognosis. Because the loading conditions in MR allow continued late ejection into a lower-impedance LA, a higher cutoff for “normal” LVEF is used in MR than in other types of heart disease. Although it is clearly inadvisable to allow patients’ LV function to deteriorate beyond the benchmarks of an LVEF ≤60% or LVESD ≥40 mm, some recovery of LV function can still occur even if these thresholds have been crossed.5,32

3. Repair success increases with surgical volume and expertise, which is a principle guiding surgical referral.21,27 However, mitral valve replacement is preferable to a poor repair. The results of a minimally invasive approach may be similar to those of a full median sternotomy if the minimally invasive operation is performed by highly experienced surgeons.33–38 When leaflet dysfunction is limited so that only annuloplasty and repair of the posterior leaflet are necessary, an operative mortality rate of <1%, long-term survival rate equivalent to that of the age-matched general population, approximately 95% freedom from reoperation, and >80% freedom from recurrent moderate or severe MR at 15 to 20 years after operation are expected.23,24,39,40

4. The onset of symptoms, LV dysfunction, or pulmonary hypertension worsens the prognosis for MR. Careful surveillance may result in timing of valve surgery before these negative sequelae occur. However, an attractive alternative strategy for treating severe chronic primary MR is to perform early mitral repair before these triggers are reached. Early mitral repair avoids the need for intensive surveillance and also obviates the possibility that patients might become lost to follow-up or delay seeing their clinician until advanced LV dysfunction has already ensued.4,13,16,22 For the early mitral repair strategy to be effective, a durable repair must be provided. An unwanted valve replacement and its attendant risks, or a failed repair necessitating reoperation, could be a complication of this
approach. Thus, there must be a high degree of certainty that a durable repair can be performed. This certainty comes from the track record of the surgical team in operating on the specific type of lesion under consideration. Thus, asymptomatic patients should be treated in a Comprehensive Valve Center.21,24,27–29 In excellent hands, patients with severe MR from flail leaflets who undergo early operation as opposed to watchful waiting have a lower risk of developing HF and lower mortality rates.4,13,15

5. MR may lead to progressively more severe MR as the initial level of MR causes LV dilation, which increases stress on the mitral apparatus, causing further damage to the valve apparatus, more severe MR, and further LV dilation—thus initiating a perpetual cycle of ever-increasing LV volumes and MR. Longstanding volume overload leads to irreversible LV dysfunction and a poorer prognosis. Patients with severe MR who develop an LVEF <60% or LVESD ≥40 mm have already developed LV systolic dysfunction.5,6 One study has suggested that for LV function and size to return to normal after mitral valve repair, the LVEF should be >64% and LVESD <37 mm.16 Thus, when longitudinal follow-up demonstrates a progressive decrease of LVEF toward 60% or a progressive increase in LVESD approaching 40 mm, it is reasonable to consider intervention.41 In severe MR, TTE is recommended at 3- to 6-month intervals or more frequently as the ventricle enlarges.

6. Mitral transcatheter edge-to-edge repair (TEER) with the anterior and posterior leaflets clipped together at ≥1 locations is safe and effective in treating severely symptomatic patients with primary MR who are at high or prohibitive surgical risk.17,18,42 Studies of TEER with a mitral valve clip have demonstrated improved symptoms and a reduction in MR by 2 to 3 grades, leading to reverse remodeling of the LV. Superior outcomes were shown with surgery versus TEER, and thus it is only the patients who are at high or prohibitive risk for surgery for whom TEER is performed.

7. Rheumatic mitral valve disease is less suitable for mitral repair compared with complex degenerative disease. Durability of the repair is limited by thickened or calcified leaflets, extensive subvalvular disease with chordal fusion and shortening, and progression of rheumatic disease. Freedom from reoperation at 20 years, even in experienced hands, is in the 50% to 60% range. In a large series from Korea, repair was accomplished in 22% of patients operated on for rheumatic disease.19 One-third of these patients who underwent repair had significant stenosis or regurgitation at 10 years. Repair of rheumatic mitral valve disease should be limited to patients with less advanced disease in whom a durable repair can be accomplished or to patients in whom a mechanical prosthesis cannot be used because of anticoagulation management concerns.43

8. Mitral valve repair is the procedure of choice for isolated severe primary MR limited to less than one-half of the posterior leaflet, and mitral valve replacement is inappropriate unless mitral valve repair has been attempted and was unsuccessful.31–14,21,22 Surgical repair of primary MR has been remarkably successful. Repair of isolated degenerative mitral disease, when leaflet dysfunction is sufficiently limited that only annuloplasty and repair of the posterior leaflet are necessary, has led to outcomes distinctly superior to those with biological or mechanical mitral valve replacement.11–14 Repair is associated with an operative mortality rate of <1%, long-term survival rate equivalent to that of age-matched general population, approximately 95% freedom from reoperation, and >80% freedom from recurrent moderate or severe (≥3) MR at 15 to 20 years after surgery.15,39 As much as one-half of the posterior leaflet may be excised, plicated, or resuspended. Posterior leaflet repair has become sufficiently standardized in this situation so that repair, rather than mitral valve replacement, is the standard of care. Execution of this procedure with a success rate ≥95% should be the expectation of every cardiac surgeon who performs mitral valve procedures.

7.3. Chronic Secondary MR

7.3.1. Stages of Chronic Secondary MR

In chronic secondary MR, the mitral valve leaflets and chords usually are normal or minimally thickened. Instead, MR is associated with severe LV dysfunction caused by CAD (ischemic chronic secondary MR) or idiopathic myocardial disease (nonischemic chronic secondary MR). The abnormal and dilated LV causes papillary muscle displacement, which in turn results in leaflet tethering with associated annular dilation that prevents adequate leaflet coaptation. Secondary MR may also develop because of LA dilation and enlargement of the mitral annulus, which often occurs with AF and other cardiomyopathies. There are instances in which both primary and secondary MR are present. The best therapy for chronic secondary MR is not clear because MR is only one component of the disease, and restoration of mitral valve competence is not curative. The optimal criteria for defining severe secondary MR have been controversial. Compared with primary MR, adverse outcomes in secondary MR are associated with a smaller
calculated ERO; the severity of secondary MR may increase over time because of adverse remodeling of the LV or mitral annulus; and Doppler methods for calculations of ERO area by the flow convergence method may underestimate severity because of the crescentic shape of the regurgitant orifice.1,2 Even so, on the basis of the criteria used for determination of “severe” MR in RCTs of surgical intervention for secondary MR,3–6 the recommended definition of severe secondary MR is now the same as for primary MR (ERO ≥0.4 cm² and regurgitant volume ≥60 mL) (Table 18).

7.3.2. Diagnosis of Chronic Secondary MR

**Recommendations for Diagnosis of Secondary MR**

Referenced studies that support the recommendations are summarized in Table 18 from the patients with secondary MR (Stages B to D), TEE is useful to establish the etiology and to assess the extent of regional and global LV remodeling and systolic dysfunction, severity of MR, and magnitude of pulmonary hypertension.1,2

<tr>
<td>1</td>
<td>C-EO</td>
<td>4. In patients with chronic secondary MR undergoing transcatheter mitral valve intervention, intraprocedural guidance with TEE is recommended.4,7,9–13</td>
</tr>
</tbody>
</table>

**Synopsis**

In symptomatic patients with chronic secondary MR, TTE is the initial diagnostic modality. Assessment of the coronary anatomy and myocardial viability may be helpful in management if ischemic MR is suspected. If transcatheter mitral valve intervention is contemplated, TEE determines suitability for the procedure and guides the procedure.1

**Recommendation-Specific Supportive Text**

1. TTE is essential in patients with MR to identify patients with primary MR and those with secondary forms of MR. In general, in patients with LV systolic dysfunction and symptoms of HF, the presence of chronic secondary MR of any severity is associated with a worse prognosis than that seen in the absence of MR. Most patients with secondary MR have global LV dysfunction, but in some patients, a limited but strategically placed wall motion abnormality may also cause chronic secondary MR. An initial TTE helps establish the cause of chronic secondary MR and also serves as a baseline for future comparisons. In patients with secondary MR, severe MR is defined as an ERO ≥40 mm², but outcome studies have shown poor prognosis in those with moderate MR (ERO ≥20 mm²).1,2

2. Prognosis is poor for both ischemic and non-ischemic MR, but ischemic MR lends itself to the possibility of revascularization and potential improvement in LV function if CAD has led to large areas of hibernating viable myocardium. Long-term results of the STICH (Surgical Treatment for Ischemic Heart Failure) trial demonstrated an improved 10-year survival rate in patients with ischemic cardiomyopathy and LVEF <35% who underwent CABG plus GDMT as compared with those randomized to GDMT alone. CT angiography is usually adequate to rule out significant CAD and thus rule out ischemic MR. If CAD is detected and noninvasive testing demonstrates areas of viability, coronary arteriography is pursued to better define the anatomy for potential revascularization.14,15 Although the presence of myocardial viability did not determine the effect of revascularization on survival in the STICH trial, there is a subset of patients with viable myocardium in whom the ischemic MR will respond to revascularization.16–18

3. Clinical trials have identified anatomic considerations, detectable by TEE, that can identify patients with secondary MR who have a valve morphology amenable to TEER. In the COAPT (Cardiovascular Outcomes Assessment of the MitraClip Percutaneous Therapy for Heart Failure Patients with Functional Mitral Regurgitation) trial of patients with secondary MR and HF, exclusion criteria included vertical coaptation length <2 mm in valves with leaflet tethering, evidence of calcification in the grasping area of the A2 or P2 scallops, presence of a significant cleft of A2 or P2 scallops, and lack of both primary and secondary chordal support. These are similar criteria to the earlier EVEREST trial. TEE is standard preprocedural imaging to determine suitability for TEER.3–8

4. During mitral TEER, TEE assists in guiding positioning of the clip(s), assessing success of the procedure, determining whether more than a single clip is necessary to reduce MR, and assuring that the clip(s) has not created MS.4,7,9–13

*Several valve hemodynamic criteria are provided for assessment of MR severity, but not all criteria for each category will be present in each patient.
Categorization of MR severity as mild, moderate, or severe depends on data quality and integration of these parameters in conjunction with other clinical evidence.
†The measurement of the proximal isovelocity surface area by 2D TTE in patients with secondary MR underestimates the true ERO because of the crescentic shape of the proximal convergence.
‡May be lower in low-flow states.
2D indicates 2-dimensional; CAD, coronary artery disease; ERO, effective regurgitant orifice; HF, heart failure; LA, left atrium; LV, left ventricular; MR, mitral regurgitation; and TTE, transthoracic echocardiogram.

Synopsis

GDMT for HF with reduced LVEF in patients with severe secondary MR should be provided, in conjunction with a cardiology expert, in the management of HF.

Recommendation-Specific Supportive Text

1. Chronic secondary MR usually develops as a result of LV systolic dysfunction. Thus, standard GDMT for HF forms the mainstay of therapy. Diuretics, beta blockers, ACE inhibitors or ARBs, and aldosterone antagonists help improve symptoms and/or prolong life in patients with HF in general and probably do so even when HF is complicated by chronic secondary MR. GDMT can reduce LV volumes (reverse remodeling) in many patients, which reduces severity of secondary MR.1-11

2. Secondary MR is often responsive to GDMT (including coronary revascularization or cardiac resynchronization therapy in appropriate patients). Optimization of GDMT should be under the supervision of a cardiology expert in the treatment of patients with HF to achieve optimal results and to determine with the MDT when symptoms are truly refractory to GDMT before decisions are made for surgical or transcatheter treatment.9,12

### Synopsis

Mitral TEER is indicated to improve symptoms and prolong life in a select subset of patients with chronic severe secondary MR, LV systolic dysfunction, and persistent severe symptoms while on optimal GDMT. Surgery may improve symptoms in these patients, with mitral valve replacement preferred over repair. A subset of patients with severe MR attributable to AF may benefit from mitral valve surgery and concomitant atrial maze procedure (Figure 9).

### Recommendation-Specific Supportive Text

1. The COAPT trial of transcatheter treatment of secondary MR demonstrated improvement in survival, hospitalization, symptoms, and quality of life in patients with persistent symptoms despite optimization of GDMT who were randomized to TEER, as compared with those randomized to continued GDMT. In contrast, MITRA-FR (Multicentre Randomized Study of Percutaneous Mitral Valve Repair MitraClip Device in Patients With Severe Secondary Mitral Regurgitation) enrolled patients with greater degrees of LV enlargement and less severe MR (mean ERO area 0.31 cm² versus 0.41 cm²) and reported no benefit of TEER in reducing the composite endpoint of death or hospitalization as compared with medical therapy. In addition, the inclusion criterion in MITRA-FR of an LVESD up to 70 mm represents extreme diastolic; in contrast, in the COAPT trial, the mean LVESD was smaller (52±9 mm), and even the LVEDD rarely exceeded 70 mm (mean 62±7 mm). Thus, the enrollment criteria in COAPT trial (LVFR between 20% and 50%, LVESD ≤70 mm, pulmonary artery systolic pressure ≤70 mmHg, and persistent symptoms [NYHA class II, III, or IV] while on optimal GDMT) are the current standard selection criteria for TEER for secondary MR. Observational studies have suggested that a greater reduction in MR severity with TEER is associated with greater LV and LA reverse remodeling.1–8,48,49 The exact anatomy and mechanism of MR also needs to be taken into consideration when determining candidacy for transcatheter repair.

2. There is no proof that surgical correction of chronic secondary MR is effective in prolonging life, but observational studies and a study of the randomized STICH trial suggest that it is wise to address the mitral valve during CABG for severe CAD when secondary MR is severe. Although it may be hoped that the revascularization will recruit hibernating myocardium and reduce chronic secondary MR, this has not been demonstrated, and failing to correct chronic severe secondary MR may leave the patient with severe residual MR. The risks and benefits of additional surgical interventions should be weighed in patients with LV systolic dysfunction.9–13

For patients with secondary MR undergoing operation for other valve disease, see Section 10.2 (Timing of Intervention for Mixed Valve Disease).  

3. MR may develop in patients with preserved LV systolic function who have progressive LA dilation, leading to enlargement of the mitral annulus and malcoaptation of the leaflets.51,52 This may arise in conditions such as HF with preserved LVEF, restrictive cardiomyopathy, and nonobstructive hypertrophic cardiomyopathy. These patients often have associated AF, which may contribute to the progression of LA and annular dilation, thus increasing the severity of MR.18,53 and successful ablation of AF may reduce or eliminate MR.54 Isolated annular dilation accounts for <20% of patients referred for surgery of severe MR in the STS database, but it is also the etiology with...
4. There is limited evidence that mitral valve surgery improves survival in symptomatic patients with secondary MR. In addition, surgery may improve symptoms and quality of life in these patients whose symptoms persist despite GDMT. Small RCTs demonstrate that mitral valve surgery reduces chamber size and improves peak oxygen consumption in chronic severe secondary MR. Ischemic or dilated cardiomyopathy presents different challenges for mitral repair. Regurgitation is caused by annular dilation, as well as by apical and lateral displacement of the papillary muscles. New techniques have facilitated mitral repair in this situation, but durability of the repair is dependent primarily on regression or progression of ventricular dilation. If the heart continues to dilate, long-term durability of the repair is moot; the survival of the patient is limited.9,12,21–43

5. In an RCT of mitral valve repair versus mitral valve replacement in patients with severe ischemic MR, there was no difference between repair and mitral valve replacement in survival rate or LV remodeling at 2 years. However, the rate of recurrence of moderate or severe MR over 2 years was higher in the repair group than in the replacement group, leading to a higher incidence of HF and repeat hospitalization. The lack of apparent benefit of valve repair over valve replacement in secondary MR versus primary MR, with less durable repairs in secondary MR, highlights that primary and secondary MR are 2 different diseases.9,12,21–32,44–47
8. TRICUSPID VALVE DISEASE

8.1. Classification and Stages of TR

Trace to mild degrees of TR of no physiological consequence are commonly detected on TTE in subjects with anatomically normal valves. However, significant or worsening TR is associated with poor long-term outcomes.1–7 Primary disorders of the tricuspid apparatus that can lead to more significant degrees of TR include rheumatic disease, IE, congenital disease (Ebstein’s), myxomatous changes, and other problems affecting the tricuspid valve leaflets (blunt chest trauma, carcinoid, drugs, and radiation) (Table 19). A growing number of patients develop significant TR from iatrogenic etiologies (device leads and endomyocardial biopsies).8–10 Most cases of significant TR are secondary and related to tricuspid annular dilation and leaflet tethering in the setting of RV remodeling because of pressure or volume overload, as seen in patients with pulmonary hypertension (primary or secondary to left-sided heart disease) or dilated cardiomyopathies.11–13 In addition, there appears to be a subgroup of patients with significant isolated TR attributable primarily to annular dilation, usually associated with AF in the absence of pulmonary hypertension or LV systolic dysfunction.2,14–18

Table 20 shows the stages of TR as defined for other valve lesions. Asymptomatic patients with severe TR (Stage C) present with an elevated central venous pressure and imaging evidence of significant TR.

Symptomatic patients with severe TR (Stage D) have symptoms of fatigue, abdominal bloating, and peripheral edema. End-organ damage, such as hepatic failure and renal failure, is an adverse consequence of Stage D TR that markedly affects survival.19–23 The severity of TR can be dynamic and dependent on changes in preload and pulmonary pressure.

Synopsis

TTE can determine the etiology of TR and its effect on the RV. Cardiac catheterization is of clinical value if the information from TTE is inadequate or discordant with the clinical presentation.6–10

Recommendation-Specific Supportive Text

1. TTE can distinguish primary TR (abnormal valve leaflets) from secondary TR (normal valve leaflets), define any associated left-sided valvular or myocardial disease, and provide an estimate of pulmonary artery systolic pressure.11–15 Characterization of the severity of TR relies on an integrative assessment of multiple parameters, as recommended by the American Society of Echocardiography and European Association of Echocardiography,1,2 but many limitations remain. In patients with TR undergoing left-sided valve surgery, an annular diastolic diameter >40 mm (or >21 mm/m²) indicates an increased risk of persistent or progressive TR after isolated mitral valve surgery.13 Pulmonary artery systolic pressure is estimated from maximal TR velocity. Assessment of RV systolic function is challenged by geometric and image acquisition constraints, as well as by variability in RV loading condition.16,17 Normal RV systolic function is defined by several parameters, including tricuspid annular plane systolic excursion >16 mm, tricuspid valve systolic annular velocity >10.0 cm/s, and RV end-systolic area <20.0 cm² or fractional area change >35%. Other imaging modalities, such as 3D TEE, magnetic resonance imaging, and CT scan, may provide more accurate information on the status of the RV.

2. When physical examination and TTE data on estimated pulmonary artery systolic pressure are either discordant or inadequate, invasive measurement of pulmonary artery pressures and pulmonary vascular resistance can be helpful to guide

**Synopsis**

Diuretic therapy treats the systemic congestion in patients with severe symptomatic TR. In patients with secondary TR, treatment of the underlying primary cause may decrease the severity of the TR.

**Recommendation-Specific Supportive Text**

1. Patients with severe TR usually present with signs or symptoms of right-sided HF, including peripheral edema and ascites. Low-salt diet and support stockings may be helpful. Diuretics can be used to decrease volume overload in these patients. Loop diuretics are typically provided and may relieve systemic congestion, but their use can be limited by worsening low-flow syndrome. Aldosterone antagonists may be of additive benefit, especially in the setting of hepatic congestion, which may promote secondary hyperaldosteronism.

2. Medical therapies for management of severe TR (Stages C and D) are limited. Attention should be focused on the underlying etiologies in patients with secondary TR. Reduction of pulmonary artery pressures and pulmonary vascular resistance with specific pulmonary vasomodulators may be helpful to reduce RV afterload and secondary TR in selected patients with pulmonary hypertension. GDMT is effective for secondary TR attributable to HF with reduced LVEF. Restoration of normal sinus rhythm may be effective for secondary TR attributable to annular dilation associated with AF.

**Synopsis**

Treatment of secondary TR is targeted at pulmonary hypertension or myocardial disease. Surgical treatment is performed for selected patients with TR at the time of surgery for left-sided valve lesions to treat severe TR (Stages C and D) and to prevent later development of severe TR in patients with progressive TR (Stage B). Surgical intervention should be considered for selected patients with isolated TR (either primary TR or secondary TR attributable to annular dilation in the absence of pulmonary hypertension or dilated cardiomyopathy). Intervention for severe isolated TR had a high reported operative mortality rate (up to 8% to 20%), but most of these interventions were performed after end-organ damage. However, outcomes of patients with severe primary TR are poor with medical management. There is renewed interest in earlier surgery for patients with severe isolated TR before the onset of severe RV dysfunction or end-organ damage. This interest is attributable to 1) an increasing number of patients presenting with right-sided HF from isolated TR, 2) more advanced surgical techniques, and 3) better selection processes, resulting in a lower operative risk with documented improvement in symptoms (Figure 10).

There is growing interest in the development of catheter-based therapies for these patients with severe isolated TR, although data on outcomes such as survival and major adverse events are lacking. Because

**Recommendation-Specific Supportive Text**

1. Severe TR of either a primary or secondary etiology may not improve predictably after treatment of the left-sided valve lesion and reduction of RV afterload; as such, severe TR should be addressed as part of the index procedure. Reoperation for severe, isolated TR after left-sided valve surgery is associated with a perioperative mortality rate of 10% to 25%. Tricuspid valve repair does not add appreciably to the risks of surgery. There has been a significant increase in the number of tricuspid valve repairs performed for this indication over the past decade. Tricuspid valve repair is preferable to replacement, but replacement may be necessary if there is marked dilation of the annulus or intrinsic disease of the tricuspid leaflets. Observational data have shown a lower operative risk with tricuspid valve repair than with replacement, but this may be related to patient selection, given that the latter would be inserted in patients with a severely dilated annulus and abnormal leaflets to prevent recurrent or residual regurgitation. The risks and benefits of tricuspid valve operation should be carefully considered in the presence of severe RV systolic dysfunction or irreversible pulmonary hypertension because of the possibility of RV failure after operation.

2. Left uncorrected at the time of left-sided valve surgery, mild or moderate degrees of secondary TR may progress over time in approximately 25% of patients and result in reduced long-term functional outcome and survival. Risk factors for persistence or progression of TR include tricuspid annulus dilation (>40 mm diameter or 21 mm/m² diameter indexed to body surface area on preoperative TTE measured at end diastole; >70 mm diameter on direct intraoperative measurement of the intercomissural distance), degree of RV dysfunction or remodeling, leaflet tethering height, pulmonary artery hypertension, AF, and intra-annular RV pacemaker or implantable cardioverter-defibrillator leads. Several observational studies and one prospective RCT have demonstrated the benefit of tricuspid repair at the time of mitral valve surgery for progressive TR (Stage B) with tricuspid annulus dilation on echocardiographic and functional parameters, although data on outcomes such as survival and major adverse events are lacking.
the severity of TR may be dynamic, dependent on the preload and pulmonary pressures, a past history of signs or symptoms of right-sided HF indicates the propensity to develop more severe TR and should be considered an indication for concomitant tricuspid valve repair.

3. In patients with symptomatic severe primary TR, reduction or elimination of the regurgitant volume load by tricuspid valve surgery can alleviate systemic venous and hepatic congestion and decrease reliance on diuretics. Patients with severe congestive hepatopathy may also benefit from surgery to prevent irreversible cirrhosis of the liver. Quality and duration of long-term survival are related to residual RV function. In patients with severe symptomatic primary TR from either device leads or endomyocardial biopsy, TR develops rapidly, and surgery can be done before the onset of RV dysfunction. Correction of symptomatic severe primary TR (Stage D) in patients without left-sided valve disease would preferentially be performed before the onset of significant RV dysfunction or end-organ damage. Randomized studies of early intervention are lacking, and the benefit might be limited by the risk of intervention, suboptimal reduction in TR severity, or suboptimal durability of currently available approaches to tricuspid valve repair and replacement.

4. There is now recognition that TR can develop in association with AF and annular dilation (a form of secondary TR). Notably, AF-related TR appears to represent a fundamentally different pathophysiology from other forms of secondary TR, with greater basal dilation and annular enlargement, as compared with the RV elongation with leaflet tethering seen in patients who have secondary TR caused by pulmonary hypertension or myocardial disease. These patients with AF-related TR have rapid progression of TR severity and right-sided chamber dilation. In appropriately selected symptomatic patients with AF-related severe TR, quality of life and symptoms can be improved by surgical intervention for TR. In patients undergoing intervention, overall outcomes are better in those without severe RV dysfunction or end-organ damage. Newer surgical techniques and a better selection process resulted in an acceptable operative mortality rate (<4% to 5%) for isolated TR in selected patients. Extrapolation from limited experiences reported for patients with stable carcinoid heart disease and patients with a flail tricuspid leaflet, as well as application of the management principles adopted for patients with severe MR, suggest that serial assessments of RV size and function might trigger consideration of corrective surgery in selected patients with severe primary TR when a pattern of continued deterioration can be established and the surgical risk is considered acceptable. In otherwise healthy patients without other comorbidities, such as patients with severe TR attributable to trauma, the surgical risk associated with tricuspid valve operation is low (<1% to 2% operative mortality).
rate) in the absence of RV dysfunction or pulmo-

erary hypertension.

6. Isolated tricuspid valve surgery for severe TR his-
torically has been performed relatively late in the
natural history of the disease, when patients have
become symptomatic with signs of right-sided HF.
Unadjusted mortality rates for isolated tricuspid valve
surgery have therefore exceeded those reported for
isolated aortic or mitral valve surgery, and this trend
has been even more pronounced for reoperative tri-
cuspid surgery late after left-sided valve surgery.1,2,39
This high reoperative mortality rate is likely related
to the advanced nature of RV failure encountered at
the time of the second procedure, residual pulmo-
nary hypertension, LV dysfunction, and other valve
abnormalities. The hazards imposed by reoperation
have influenced decision-making for initial repair of
functional TR at the time of left-sided valve surgery
in an attempt to prevent the development of severe
TR later after the left-sided valve surgery. However,
if there is no significant pulmonary hypertension or
severe RV systolic dysfunction, operation for severe
symptomatic isolated TR years after surgery for left-
sided disease may improve symptoms of right-sided
HF, if done before the onset of severe RV dysfunc-
tion or end-organ damage with either hepatic or
renal dysfunction.11,18

Synopsis

Mixed valve disease is either 1) stenosis and regurgita-
tion of a single valve or 2) stenosis or regurgitation of 2
separate valves. Mixed valve disease presents a special
diagnostic challenge to the clinician in assessing the im-
pact of the lesions on cardiac remodeling, ventricular

function, and timing of intervention.1–5 For many pa-
tients with mixed valve disease, there is a predominant
valve lesion (ie, stenosis versus regurgitation; mitral
versus aortic), and symptoms and pathophysiology re-
semble those of a pure dominant lesion. When pres-
sure overload predominates, there is usually concentric
hypertrophy, whereas volume overloads cause chamber
dilation and eccentric hypertrophy; management should
follow the guidelines for the predominant lesion. How-
ever, in other cases, patients present with a more bal-
anced picture, with the mixed pathophysiology making
patient management difficult. It may be that neither
lesion by itself reaches Stage C as described in previ-
ous sections for pure lesions, yet the lesions may be, in
combination, severe enough to impact outcome. Mixed
valve disease was primarily attributable to rheumatic
disease in the past, but it is now more frequently seen
with degenerative disease or after prior chest radiation.5
Decision-making for patients with mixed valve disease is
frequently complex and may require referral to or con-
sultation with a Comprehensive Valve Center.

Recommendation-Specific Supportive Text

1. The complex nature of mixed valve disease
requires a comprehensive imaging approach that
involves assessing each lesion separately and then
collectively judging how the lesions affect the
patient’s overall presentation. TTE is the standard
modality for measuring jet velocities, valve areas,
regurgitant flow, and regurgitant orifice areas. TTE
establishes the baseline for pathoanatomy and pathophysiology from which comparison is
made as the lesions progress over time. Doppler
hemodynamics have been validated for patients
with single-valve disease but have not necessarily
been studied in patients with multivalve disease.
Limitations exist for assessment of calculations,
such as those for valve areas, because of differen-
tial flows with multivalve disease.2–5

2. The complex nature of mixed valve disease
makes it necessary to consider all available
data to reach a final management decision.
Although natural history data for many types of
mixed valve disease are lacking, it is reasonable
to assume that the onset of symptoms is a neg-
ative prognostic occurrence, as it is for all other
valve lesions. The difficulty may lie in attribut-
ing such symptoms to the mixed valve disease
at hand, especially if TTE demonstrates moder-
ate but not severe mixed disease. Elevated BNP
and elevated filling pressures at catheterization,
either at rest or with exercise, support that car-
diac disease is the cause of the patient’s symp-
toms and may help to further quantify lesion
severity.
10.2. Timing of Intervention for Mixed VHD

10.2.1. Intervention for Mixed AS and AR

**Synopsis**

The indications for AVR in patients with combined AS and AR and a peak transvalvular jet velocity of ≥4.0 m/s are the same as for patients with severe isolated AS.

**Recommendation-Specific Supportive Text**

1. Currently, isolated moderate AS or moderate AR is placed in Stage B, progressive disease for which no therapeutic action is indicated. However, some patients with moderate mixed disease develop symptoms that stem from their valve disease. Formerly, the argument was raised that if there were no AR, the aortic jet velocity and gradient would be correspondingly lower and would not meet the definitions for severe AS, and obviously there would be only moderate AR by definition. Therefore, no action was recommended. However, recent data suggest that the natural history of moderate mixed disease behaves similarly to that of pure severe AS and that moderate mixed disease has a mortality risk similar to that of pure severe AS. Thus, valve replacement is warranted for the symptomatic patient if the patient’s data fulfill any of the criteria for severe AS. The decision about whether to proceed with TAVI versus SAVR is discussed in Section 3.2.4.2.

2. For patients with mixed moderate AS/AR who have developed LV dysfunction, as evidenced by an LVEF of <50%, and who have no other reason for LV dysfunction, valve disease is presumed to be the cause. In such patients, SAVR is indicated.1, 2

**10.2.2. Intervention for Mixed AS and MR**

Patients with combined AS and MR present a difficult and complex decision-making process. There are many potential different scenarios and nuances involved to arrive at the optimal approach for an individual patient, which needs to be made by an MDT with shared decision-making with the patient. Overall, patients with severe AS and severe primary MR are best treated with SAVR and mitral valve surgery unless the surgical risk is high or prohibitive. If there is a high or prohibitive surgical risk, a staged procedure, with TAVI followed by mitral TEER, can be effective. If there is severe AS and severe secondary MR, either SAVR and mitral valve surgery or a staged approach with TAVI followed by mitral TEER are options. Because there are limited data to support COR, the writing committee has created a table that provides the reader with a perspective on possible interventions in these complex patients (Table 21). Evaluating the short- and long-term outcomes of these approaches will be important.

These proposed procedures are based on the following:

- Many patients with AS also have significant MR that is attributable to either organic (primary) causes or LV remodeling (secondary MR). AVR for AS reduces LV pressure, thereby reducing the pressure gradient that propels volume across the incompetent mitral valve. Although it is reasonable to expect that AVR would reduce MR by reducing LV systolic pressure, this fails to occur in many cases. Not surprisingly, primary MR is more likely to persist after AVR than is secondary MR because AVR does not correct intrinsic mitral valve disease.1-5 Therefore, in patients with both AS and MR who are at a low or intermediate surgical risk, it is reasonable to address both valves with surgery. This is particularly true if the mitral valve can be repaired.1

- For patients with both AS and severe primary MR in whom the mitral valve cannot be repaired, a decision about treatment of the MR will need to be made by the MDT, taking into consideration multiple factors, including the additive risk of a mitral valve replacement. Mitral TEER at a later date may be an option but is likely to have a suboptimal result if the valve cannot be surgically repaired. Thus, double valve replacement with both AVR and mitral valve replacement would be an option if they can be performed at an acceptable level of risk, given that the outcome of the MR after AVR is uncertain.

- Patients with severe AS who are at high to prohibitive surgical risk are best served by TAVI. As noted previously, primary MR may not improve after AVR.2-5 If symptoms persist after TAVI and if there is suitable anatomy, percutaneous mitral repair can be performed, which can reduce MR and improve symptoms.6

- For patients with AS who have secondary MR, the fate of MR after SAVR or TAVI is uncertain.2-5, 7-10 Although secondary MR is more likely to improve after AVR than is MR attributable to primary mitral valve disease, secondary MR does not improve or may even worsen after AVR in many cases.7-10 The mechanism by which reduction in LV pressure after
limits LV filling, it may reduce the stroke volume presented to the aortic valve, in turn reducing the apparent severity of AR. Furthermore, MS reduces the LV cavity size for any degree of AR, causing further potential underestimation of AR severity. In this regard, contrast aortography visualizes AR flow, instead of the echocardiographic visualization of AR velocity of flow, and may be helpful, as is precise assessment of AR regurgitant fraction. In patients who have continued severe symptoms not responsive to diuretics, intervention with valve surgery should be pursued. If mitral anatomy is favorable, options are PMBC to treat the MS, followed by AVR or SAVR and open mitral commissurotomy. In this way, the increased mortality risk of double valve replacement is avoided.

10.2.5. Intervention for Mixed MS and AS
Almost always the product of rheumatic heart disease, the combination of MS and AS can be very confusing to the clinician. When either lesion is severe, it may limit cardiac output, resulting in reduced flow to the other valve, which reduces transvalvular gradient, leading to underestimation of lesion severity. Echocardiography and invasive hemodynamics are usually necessary to fully assess the severity of each lesion and to decide on appropriate intervention.

*Consider TEER as a later staged procedure if symptoms and severe MR persist after treatment of the AS.

AS indicates aortic stenosis; MR, mitral regurgitation; SAVR, surgical aortic valve replacement; TAVI, transcatheter aortic valve implantation; and TEER, transcatheter edge-to-edge repair.

10.2.3. Intervention for Mixed MS and MR
Mixed MS and MR often occurs in patients with rheumatic valve disease. Occasionally, mixed MS/MR can occur in patients with severe mitral annular calcification. Asymptomatic mixed disease may be benign because MS protects the LV from the severe volume overload of pure MR. However, if symptoms attributable to mixed mitral disease occur, they are likely because of increased LA pressure from combined increased LA inflow from MR and obstruction to outflow from the LA. An enlarged LA, a high transmitral gradient, or direct measurement of a high LA or pulmonary artery wedge pressure suggest a valvular basis for the patient's symptoms. In such cases, mitral valve replacement may be necessary if therapy with diuretics do not relieve symptoms, but it should be performed only in patients who have severe limiting symptoms.

10.2.4. Intervention for Mixed MS and AR
Combined MS and AR usually result from rheumatic heart disease. When they occur concomitantly, MS is usually the more severe lesion. However, because MS
**Synopsis**

The clinical course of patients with prosthetic heart valves or repaired native valves is influenced by several factors, including ventricular function, AF, pulmonary hypertension, and CAD, as well as by the development of valve-related complications. The interval between routine follow-up visits depends on the patient’s valve type, the presence of residual heart disease, and other clinical factors. Attention to optimal dental care and endocarditis prophylaxis and any needed anticoagulation is a requisite component of care.

TTE is the primary imaging modality for postoperative assessment of prosthetic valve or repaired native valve function. In the absence of early complications, the index study is performed during hospitalization or within the first several weeks thereafter, depending on individual patient circumstances and the type of valve procedure. Additional imaging, such as TEE, cardiac CT, or fluoroscopy, may be required when valve dysfunction is suspected and in the context of the clinical presentation. A schedule for surveillance TTE studies has become an established feature of long-term follow-up, although the frequency of routine studies that are performed in the absence of clinical change will vary as a function of valve type.

**Recommendation-Specific Supportive Text**

1. TTE after valve implantation or repair provides an assessment of the procedural results and serves as a baseline against which comparison can be made for any change. TTE provides accurate measurements of transvalvular velocities and pressure gradients, as well as detection and quantitation of transvalvular and paravalvular leak.1–4 Normal transvalvular velocities and gradients vary across different types and sizes of prosthetic valves but are also affected by patient-specific factors, including body size and cardiac output. The postoperative study, recorded when the patient is asymptomatic and in a stable hemodynamic state, provides Doppler flow data for a specific valve in an individual patient. In addition, TTE provides assessment of other valve disease(s), pulmonary artery pressure, atrial size, LV and RV size and function, and pericardial disease.

2. Bioprosthetic or repaired native valve dysfunction typically presents with the insidious onset of HF symptoms or a change in the auscultatory findings. More abrupt and severe symptoms may occur with infective endocarditis or rupture of a valve cusp. Patients with mechanical valve dysfunction may present with HF, shock, thromboembolic events, hemolysis, or a change in auscultatory findings. Presentation may often be acute or subacute because of thrombus formation and more abrupt impairment of leaflet opening or closure. Attention should be directed to the trend in recent INR determinations. Prosthesis–patient mismatch and functional stenosis of a repaired native valve are also to be considered in the evaluation of patients with HF symptoms. Repeat noninvasive assessment begins with transthoracic echocardiography, comparison with the index postoperative study when available, and the use of other modalities as dictated by the clinical context and preliminary findings.

3. TTE is the preferred approach for initial assessment of suspected prosthetic valve dysfunction because it allows for measurement of transvalvular velocity, gradient, and valve area. TTE also allows quantitation of LV volumes and LVEF, an estimate of pulmonary artery systolic pressure, and evaluation of right heart function. However, the LA side of a prosthetic mitral valve is obscured by acoustic shadowing from the TTE approach, resulting in reduced sensitivity for detection of prosthetic MR and prosthetic mitral valve thrombus, pannus, or vegetation. TEE provides superior imaging of the LA side of the mitral prosthesis and is accurate for diagnosis of prosthetic mitral valve dysfunction.5,6 Both TTE and TEE are also needed for patients with prosthetic aortic valves in whom the posterior aspect of the valve is shadowed on the TTE approach and the anterior aspect of the valve is shadowed on the TEE approach.7,8 TEE has superior sensitivity for the detection of vegetations and abscess formation in patients with suspected prosthetic valve (or annuloplasty ring) endocarditis. With mechanical valve obstruction, fluoroscopy or CT imaging can also be helpful for detection of reduced motion caused by pannus ingrowth or thrombus.

4. Studies based on TTE follow-up estimate that approximately 30% of patients with a surgical aortic valve bioprosthesis develop evidence of valve dysfunction over the 10 years after implantation (defined as an increase in mean gradient of ≥10 mm Hg or a worsening of transprosthetic regurgitation from mild to moderate or from moderate to severe).9 The incidence of clinically important structural valve deterioration increases markedly more than 10 years after surgery, such that routine annual TTE studies thereafter are reasonable.10,11 Risk factors associated with accelerated (<5 years) valve deterioration include young age (<60 years) at implantation, smoking, diabetes mellitus, chronic kidney disease, initial mean gradient ≥15 mm Hg, and valve type.9,12 The selective adoption of an earlier, annual TTE screening program may be considered for at-risk patients on an individual basis, as up to 13% of patients...
with a surgical aortic valve develop hemodynamic valve dysfunction at a median of 6.7 to 9.9 years after implantation. Patients typically remain asymptomatic until valve dysfunction is severe enough to result in adverse hemodynamic consequences or AF. Depending on the valve type and mechanism of regurgitation, some patients with asymptomatic, significant prosthetic valve regurgitation may require reintervention. For example, if prosthetic regurgitation is attributable to a bioprosthetic leaflet tear, more severe acute regurgitation may occur suddenly and cause clinical decompensation. With prosthetic valve stenosis, TTE diagnosis while the patient is asymptomatic alerts the clinician to the need for more frequent follow-up. A standardized definition and grading system for structural valve deterioration for surgical and transcatheter aortic valves have been proposed. In patients with mechanical valve prostheses, routine annual TTE evaluation is not needed if the postoperative baseline study is normal and no clinical change is apparent. Many of these patients require TTE studies for other indications, however, such as for the assessment of LV function, pulmonary artery pressure, or other cardiac or valve disease.

5. Durability data for bioprosthetic TAVI valves are less robust than the data for surgically implanted bioprosthetic valves. To date, the intermediate-term durability of TAVI valves has compared favorably with that of SAVR valves, as reported in randomized trials and registries. For the most part, these data reflect observations made in older patients and may not be applicable to younger populations (eg, <70 years). TAVI-based protocols typically include routine TTE before discharge and at 30 days and 1 year, in part because of reporting requirements. In the absence of clinical change, routine annual TTE studies are reasonable as experience continues to accumulate.

Synopsis

Shared decision-making about the choice of prosthetic valve type is influenced by several factors, including patient age, values, and preferences; expected bioprosthetic valve durability, avoidance of patient–prosthesis mismatch, and the potential need for and timing of reintervention; and the risks associated with long-term VKA anticoagulation after a mechanical valve replacement. (See also Section 3.2.4 regarding valve choice in patients with AS.) Despite the significantly higher rate of bioprosthetic structural valve deterioration observed in younger versus older patients,2–12,15, many younger patients choose to avoid a mechanical prosthesis because they are unwilling to consider long-term VKA therapy because of the inconvenience of monitoring, dietary restrictions, medication interactions, and the need to restrict participation in some types of athletic activity. A mechanical valve might be a prudent choice for patients for whom a second surgical procedure would be very high risk (eg, those with prior radiation exposure). The availability of TAVI has changed...
the dynamics of the discussion of the trade-offs between mechanical and bioprosthetic valves in younger patients (Table 22) (Figure 11).16–19

Recommendation-Specific Supportive Text

1. The choice of valve prosthesis in each patient is based on consideration of several factors, including valve durability, expected hemodynamics for valve type and size, surgical or interventional risk, the potential need for long-term anticoagulation, and patient values and preferences. The trade-off between the risk of reintervention for bioprosthetic valve deterioration and the risk of long-term anticoagulation should be discussed. Some patients prefer to avoid repeat surgery and are willing to accept the risks and inconvenience of lifelong anticoagulant therapy. Other patients are unwilling to consider long-term anticoagulation because of the inconvenience of monitoring, the attendant dietary and medication interactions, and the need to restrict participation in some types of physical activity. The incidence of structural deterioration of a bioprosthesis is greater in younger patients, but the risk of bleeding from anticoagulation is higher in older patients. In patients with shortened longevity or multiple comorbidities, a bioprosthesis might be more appropriate. In women who desire subsequent pregnancy, the issue of anticoagulation during pregnancy is an additional consideration (see pregnancy-related issues in Section 13.5).20,21

2. Anticoagulant therapy with VKA is necessary in all patients with a mechanical valve to prevent valve thrombosis and thromboembolic events. If anticoagulation is contraindicated or if the patient refuses VKA therapy, an alternative valve choice is appropriate. Newer anticoagulant agents have not been shown to be safe or effective in patients with mechanical heart valves.

3. Patients <50 years of age at the time of AVR incur a higher and earlier risk of bioprosthetic valve deterioration.4,10,11,22–24 Overall, the predicted 15-year risk of needing reoperation because of structural deterioration is 22% for patients 50 years of age, 30% for patients 40 years of age, and 50% for patients 20 years of age, although it is recognized that all bioprostheses are not alike in terms of durability.11 Anticoagulation with a VKA can be accomplished with acceptable risk in most patients <50 years of age, particularly in compliant patients with appropriate monitoring of INR levels. Thus, the balance between valve durability and risk of bleeding and thromboembolic events favors the choice of a mechanical valve in patients <50 years of age, unless anticoagulation is not desired, cannot be monitored, or is contraindicated.

4. Uncertainty and debate continue about which type of AVR is appropriate for patients 50 to 65 years of age. Newer surgical bioprosthetic valves may show greater freedom from structural deterioration, specifically in the older individual, although a high late mortality rate in these studies may preclude recognition of valve dysfunction.11,15–19 The risks of bleeding and thromboembolism with mechanical prostheses are low, especially in compliant patients with appropriate INR monitoring. Several studies have shown a survival advantage with a mechanical prosthesis in this age group. Alternatively, large retrospective observational studies have shown similar long-term survival rates in patients 50 to 69 years of age undergoing mechanical versus bioprosthetic valve replacement.22–24 In general, patients with mechanical valves experience a higher risk of bleeding because of anticoagulation, whereas individuals who receive bioprosthetic valves experience a higher rate of reoperation attributable to structural deterioration of the prosthesis, as well as perhaps a decrease in survival rate.6,25–27 Several other factors should be considered in the choice of type of valve prosthesis (see Section 11.1). Ultimately, the choice of mechanical versus

AF indicates atrial fibrillation; AVR, aortic valve replacement; INR, international normalized ratio; TAVI, transcatheter aortic valve implantation; ViV, valve-in-valve; and VKA, vitamin K antagonist.
bioprosthetic valve replacement for all patients, but especially for those between 50 and 65 years of age, should be made in a shared decision-making process that must account for the trade-offs between durability (and the need for reintervention), bleeding, and thromboembolism.1

5. In patients >65 years of age at the time of bioprosthetic AVR, the likelihood of primary structural deterioration at 15 to 20 years is only about 10%.28–31 In addition, older patients are at higher risk of bleeding complications related to VKA therapy and more often require interruption of VKA therapy for noncardiac surgical and interventional procedures. It is reasonable to use a bioprosthetic valve in patients >65 years of age to avoid the risks of anticoagulation because the durability of the valve exceeds the expected years of life.

6. In general, patients with mechanical valve replacement experience a higher risk of bleeding because of anticoagulation, whereas individuals who receive a bioprosthetic valve replacement incur a higher risk of repeat intervention attributable to structural valve deterioration. In patients <65 years of age, observational data suggest better long-term outcomes with a mechanical mitral valve replacement, even when the risks and inconvenience of long-term VKA anticoagulation are considered. In a propensity-matched analysis from New York’s Statewide Planning and Research Cooperative System (SPARCS), although there was no survival difference for patients 50 to 69 years of age undergoing mechanical versus bioprosthetic mitral valve replacement,7 the rates of reoperation were lower (HR: 0.59) with a mechanical valve, though stroke risk (HR: 1.62) was higher. In the 2017 report from the California Office of Statewide Health Planning and Development,1 for patients who underwent mitral-valve replacement and were 40 to 69 years of age, receipt of a biological prosthesis was associated with a mortality rate significantly higher than that seen with receipt of a mechanical prosthesis.1 The choice of a mechanical mitral valve in patients <65 years of age who are good candidates for anticoagulation should account for these observational, nonrandomized data and abide by the principles of shared decision-making.1,7,10

7. Hazards associated with anticoagulation increase with age, and rates of structural valve deterioration decline significantly. In patients >65 years of age, the ratio of valve durability to life expectancy supports the use of a bioprosthetic mitral valve replacement, which allows avoidance of the risks of long-term VKA anticoagulation in these older patients. In

**Synopsis**

Antithrombotic therapy after prosthetic valve implantation is provided to prevent valve/leaflet thrombosis and reduce the incidence of thromboembolic complications. The use of any strategy must be balanced against the risk of bleeding. VKAs remain the cornerstone of therapy.
for patients with mechanical valve prostheses. Oral antithrombin and anti-Xa agents are not approved for use in these patients. The addition of mono- or dual-antiplatelet therapy to VKA treatment for other indications (eg, acute coronary syndrome or percutaneous coronary intervention [PCI]) must be done with caution. The evidence base for the optimal antithrombotic strategy across subgroups of patients who have received a bioprosthetic valve is not robust. Practice patterns around the use of antiplatelet and anticoagulant medications in these patients vary as a function of method of implantation (surgical versus transcatheter), the presence of any independent indication for anticoagulation (eg, AF, venous thromboembolic disease), and local/institutional care pathways (Figure 12).

**Recommendation-Specific Supportive Text**

1. All patients with mechanical valves require lifelong anticoagulant therapy with a VKA.\(^1\)\(^-\)\(^5\) In addition to the thrombogenicity of the intravascular prosthetic material, mechanical valves impose abnormal flow conditions, with zones of low flow within their components, as well as areas of high-shear stress, which can cause platelet activation that leads to valve thrombosis and embolic events. Therapy with an oral VKA at an INR goal appropriate for the comorbidity of the patient and the type and position of the mechanical valve prosthesis is required to decrease the incidence of thromboembolism and associated morbidity. Data show that anticoagulation with a VKA is protective against valve thrombosis (OR: 0.11; 95% CI: 0.07–0.17) and thromboembolic events (OR: 0.21; 95% CI: 0.16–0.27). It is preferable to specify a single INR target for each patient and to recognize that the acceptable range includes 0.5 INR units on each side of this target. A specific target is preferable because it reduces the likelihood of patients having INR values consistently near the upper or lower boundary of the range. Fluctuations in INR are associated with an increased incidence of complications in patients with prosthetic heart valves.\(^1\)\(^9\)\(^,\)\(^3\)\(^8\)

2. The rate of thromboembolism in patients with a bileaflet mechanical AVR treated with a VKA is estimated to be 0.53% per patient-year over the INR range of 2.0 to 4.5. In a large retrospective study, adverse events increased if the INR was ≥4.0 in patients with a mechanical AVR. In patients with a current-generation mechanical AVR without other risk factors for thromboembolism, in the group treated to an INR of 2.0 to 3.0, the risk of thromboembolic events was similar to, but the risk of bleeding lower than, those of the group treated to an INR of 3.0 to 4.5 (\(P<0.01\)).\(^7\) In a randomized trial comparing moderate-intensity (INR 2.0–3.0) with high-intensity (INR 3.0 to 4.5) oral anticoagulation in patients with a single mechanical valve replacement, there was no difference in embolic events but a reduction in bleeding with the moderate-intensity group.\(^9\) In a study comparing an INR target of 1.5 to 2.5 with a target of 2.0 to 3.0 in patients with current-generation mechanical aortic prosthetic valves and no other thromboembolic risk factors, the lower INR target range was noninferior, but the quality of the evidence was low.\(^6\) For current-generation mechanical valve prostheses in the aortic position, an INR of 2.5 (range, 2.0–3.0) provides a reasonable balance between the risks of thromboembolism and bleeding.\(^8\)\(^,\)\(^9\)

3. In patients with an aortic mechanical prosthesis who are at higher risk of thromboembolic complications, the INR should be maintained at 3.0 (range, 2.5–3.5). Risk factors include AF, previous thromboembolism, hypercoagulable state, and older-generation prosthesis (eg, ball-in-cage).\(^10\) Severe LV dysfunction may also increase thromboembolic risk.\(^9\)

4. The incidence of thromboembolism is higher with mitral than with aortic mechanical valves, and it is lower in mitral mechanical valve patients with a higher rather than a lower INR. In the GELIA (German Experience with Low Intensity Anticoagulation) study of patients with a mechanical mitral prosthesis, a lower INR range (2.0–3.5) was associated with a lower survival rate than that seen with a higher target INR range (2.5–4.5).\(^11\) Patient compliance may be challenging with higher INR goals. In one study, patients with a target INR between 2.0 and 3.5 were within range only 44.5% of the time. In contrast, patients with a target INR of 3.0 to 4.5 were within range only 44.5% of the time. An INR target of 3.0 (range, 2.5–3.5) provides a reasonable balance between the risks of under- or over-anticoagulation in patients with a mechanical mitral valve.\(^9\)

5. Prior recommendations about the use of antiplatelet therapy after TAVI were derived from the protocols used in the pivotal randomized studies showing the safety and effectiveness of this technology. These protocols were in turn adopted from studies of patients undergoing PCI. The small and underpowered ARTE trial (Aspirin Versus Aspirin plus Clopidogrel Following Transcatheter Aortic Valve Implantation) suggested that single-agent therapy, compared with dual-agent therapy, tended to reduce the risk of major adverse events (death, myocardial infarction, stroke, transient ischemic attack, and major or life-threatening bleeding) after TAVI. Whereas there were no
differences between the groups with respect to death, stroke, or myocardial infarction, dual therapy was associated with a significantly increased risk of major or life-threatening bleeding. A systematic review and meta-analysis comprising approximately 2500 patients suggested that single-agent therapy is associated with fewer 30-day deaths and less major bleeding than is seen with dual-agent therapy. There are several ongoing trials on this subject.

6. The risk of thromboembolism is approximately 0.7% per year in patients with biological valves in sinus rhythm; Figure 13 is derived from several studies in which most patients were not undergoing therapy with VKA. Among patients with bioprosthetic valves, those with a mitral prosthesis have higher rates of thromboembolism than do those with an aortic prosthesis (2.4% per patient-year versus 1.9% per patient-year). In studies of patients with bioprosthetic aortic valves who were in sinus rhythm and had no other indications for anticoagulation, the incidence of thromboembolic events, bleeding, and death was similar in those who received aspirin or aspirin-like antiplatelet agents only and in those who received VKA. There are no studies examining the long-term effects of antiplatelet agents in patients with bioprosthetic mitral valve repair or mitral valve repair; the beneficial effects seen with bioprosthetic aortic valves may apply to mitral valves, as well.

7. Many patients who undergo surgical implantation of a bioprosthetic mitral or aortic valve will not require lifelong anticoagulation in the absence of an independent indication, such as AF. However, there is an increased risk of ischemic stroke early after operation, particularly in the first 90 to 180 days after either bioprosthetic AVR or mitral valve replacement. Anticoagulation early after valve implantation is intended to decrease the risk of thromboembolism until the prosthetic valve is fully endothelialized. The potential benefit of anticoagulation therapy must be weighed against the risk of bleeding. In a nonrandomized
study, patients with a bioprosthesis who received anticoagulation had a lower rate of thromboembolism than that of those who did not receive therapy with VKA.\textsuperscript{15} Even with routine anticoagulation early after mitral valve surgery, the incidence of ischemic stroke within the first 30 postoperative days was higher after replacement with a biological prosthesis than after mitral valve repair (1.5%±0.4%) or replacement with a mechanical prosthesis.\textsuperscript{21} Small studies have not established a convincing net benefit of anticoagulation after implantation of a bioprothetic AVR\textsuperscript{24,25}; however, a large observational Danish registry demonstrated a lower risk of stroke and death with VKA, which extended up to 6 months, without a significantly increased bleeding risk.\textsuperscript{20} Concern has been raised about the incidence of subclinical bioprosthetic valve leaflet thrombosis after surgical valve replacement.\textsuperscript{19} In addition, the PARTNER 2 (Placement of Aortic Transcatheter Valves) investigators reported that the use of anticoagulation after bioprosthetic AVR in intermediate– or higher–surgical risk patients was safe and associated with a significant reduction in 6-month stroke rates.\textsuperscript{23} Ninety-five percent of the anticoagulated patients in this registry were discharged on warfarin in preference to a direct oral anticoagulant.

8. The prior recommendation to add low-dose aspirin to therapeutic VKA therapy for a mechanical valve prosthesis was based on studies performed decades ago that included many patients with older-generation prostheses who also had additional thromboembolic and vascular risk factors. A 2013 Cochrane Systematic Review showed that compared with anticoagulation alone, the addition of an antiplatelet agent reduced the risk of thromboembolic events and the total mortality rate but at the cost of an increased and offsetting risk of major bleeding.\textsuperscript{26} The authors pointed out that the quality of the included trials tended to be low, possibly reflecting the era when most trials were conducted. An individualized approach that takes the risk of bleeding into account is required.

9. In patients without risk factors who receive a mechanical On-X aortic heart valve (On-X Life Technologies Inc., Austin, Texas), targeting the INR to a lower goal (1.5–2.0) in conjunction with aspirin 81 mg daily may be a strategy for long-term management. Warfarin dosing is targeted to an INR of 2.5 (range, 2.0–3.0) for the first 3 months after surgery, during which low-dose aspirin is also used.\textsuperscript{27} This recommendation is based on a single RCT\textsuperscript{27} of lower– versus standard-intensity VKA therapy (with low-dose aspirin) in patients undergoing On-X AVR. The lower-intensity INR group experienced significantly less major and minor bleeding, whereas the rates of stroke, transient ischemic attack, total neurological events, and all-cause mortality were similar between the 2 groups. A subsequent publication from these investigators showed harm with a strategy of dual-antiplatelet therapy versus low-intensity anticoagulation plus low-dose aspirin.\textsuperscript{28}

10. The routine use of dual-antiplatelet therapy for 6 months after TAVI, which has been the default strategy since the introduction of this technology into clinical use, has been not been rigorously assessed (see previous discussion). There are several ongoing trials evaluating antithrombotic strategies after TAVI. A small, single-center RCT of patients receiving a self-expanding TAVI device showed no difference in a composite endpoint of major adverse cardiac and cerebrovascular events or life-threatening bleeding with aspirin plus clopidogrel versus aspirin alone at 30 days and 6 months.\textsuperscript{29} Compared with single-agent therapy, dual-antiplatelet therapy may be associated with a higher risk of bleeding and no significant difference in rates of valve leaflet thrombosis, thromboembolism, or valve performance.\textsuperscript{12,13} Other procedural and patient factors may impact the decision to use dual-antiplatelet therapy.

11. The selective use of VKA therapy might be considered after TAVI in patients at low bleeding risk on an individual basis. The PARTNER 2 investigators reported that the use of an anticoagulant (95% warfarin) after TAVI in intermediate– or higher–surgical risk patients was associated with a lower incidence of an increase in mean gradient >10 mmHg over the first year after implantation.\textsuperscript{23} This Doppler finding may reflect the development of leaflet thrombosis, for which a change in the frequency of follow-up examinations or treatment could be considered. VKAs may be more effective than direct oral anticoagulants for reduction of death, myocardial infarction, and cerebrovascular events in patients undergoing TAVI with an indication for anticoagulation.\textsuperscript{33} The selective short-term use of VKAs after ViV TAVI is predicated on the observation that valve thrombosis may be more frequent in this patient population.\textsuperscript{32}

12. The GALILEO (Global Study Comparing a Rivaroxaban-based Antithrombotic Strategy to an Antiplatelet-based Strategy after Transcatheter Aortic Valve Replacement to Optimize Clinical Outcomes) trial assessed a strategy of low-dose rivaroxaban (10 mg daily) plus low-dose aspirin (75–100 mg daily) versus an antiplatelet strategy
of low-dose aspirin plus clopidogrel (75 mg daily). The study was terminated prematurely by the Data and Safety Monitoring Board because of safety concerns. The rivaroxaban strategy was associated with a higher risk of death or thromboembolic complications and a higher risk of bleeding than those seen with the antiplatelet-based strategy.  

13. Dabigatran was compared with warfarin in the RE-ALIGN (Randomized, Phase II Study to Evaluate the Safety and Pharmacokinetics of Oral Dabigatran Etxilate in Patients after Heart Valve Replacement) trial. It was stopped prematurely for excessive thrombotic and bleeding complications in the dabigatran arm.  

14. The safety and efficacy of conventional-dose oral anti-Xa agents in patients with a mechanical valve prosthesis have not been evaluated.

Recommendation-Specific Supportive Text

1. Antithrombotic therapy should not be stopped for procedures in which bleeding is unlikely or would be inconsequential if it occurred (e.g., surgery on the skin, dental cleaning, or simple treatment for dental caries). Eye surgery, particularly for cataracts or glaucoma, is usually associated with very little bleeding and thus is frequently performed without alteration of anticoagulation with a VKA.

2. In patients with a bileaflet mechanical AVR and no other risk factors, the risk of thromboembolism after stopping anticoagulation with a VKA is small if the drug is withheld for only a few days. In these low-risk patients, the inconvenience and expense of bridging anticoagulation can be avoided. When it is necessary to interrupt VKA therapy, the agent is stopped 2 to 4 days before the procedure and restarted as soon as bleeding risk allows, typically 24 hours after surgery.\(^2\)\(^3\)

3. In patients with mechanical valves on long-term VKA therapy who require emergency surgery or invasive procedures, anticoagulation can be reversed by administration of intravenous prothrombin complex concentrate. It replaces the coagulation factors that are decreased by VKAs and contains all coagulant factors, including II, VII, IX, and X, in inactivated form. Onset of effect is within 5 to 15 minutes, and duration of effect persists for 12 to 24 hours. With fresh frozen plasma, onset of effect is longer (1–4 hours), and duration of effect is shorter (<6 hours), depending on the dose given. The effect of prothrombin complex concentrate can be prolonged with vitamin K, if indicated.\(^4\)

4. Although the large phase III trials comparing NOACs with warfarin excluded patients with moderate to severe rheumatic MS or mechanical heart valves, some did include patients with other VHD and bioprosthetic valve replacement or repair.\(^5\) Many patients who develop an indication for anticoagulation late after bioprosthetic heart valve replacement or native valve repair are treated safely with direct oral anticoagulants, as predicted on their CHA\(_2\)DS\(_2\)-VASc score and the predicted risks of bleeding. Considerations about the need for bridging therapy in these individuals can follow the same strategy applied to other subsets of patients who have AF without moderate to severe rheumatic MS or a mechanical prosthesis.

5. When interruption of oral VKA therapy is deemed necessary, the agent is usually stopped 3 to 4 days before the procedure and is restarted postoperatively as soon as bleeding risk allows. Bridging anticoagulation with intravenous UFH or subcutaneous LMWH is started when the INR falls below the therapeutic threshold (ie, 2.0 or 2.5, depending on the clinical context), usually 36 to 48 hours before surgery, and is stopped 4 to 6 hours (for intravenous UFH) or 12 hours (for subcutaneous LMWH) before the procedure. There are no randomized comparative-effectiveness trials evaluating a strategy of bridging versus no bridging in adequate numbers of patients with prosthetic heart valves who need temporary interruption of oral anticoagulant therapy, although such studies are ongoing. The evidence cited to support bridging therapy derives from cohort studies with poor or no comparator groups.\(^1\)\(^6\)\(^–\)\(^14\) In patient groups other than those with mechanical heart valves, increasing concerns have surfaced that bridging therapy exposes patients to higher bleeding risks without reducing the risk of thromboembolism.\(^15\) Accordingly, decisions about bridging should be individualized and should account for the trade-offs between thrombosis and bleeding.
11.4. Excessive Anticoagulation and Serious Bleeding With Prosthetic Valves

**Synopsis**

Excessive VKA anticoagulation greatly increases the risk of hemorrhage. However, a rapid decrease in INR to a subtherapeutic level may increase the risk of thromboembolism. Nevertheless, for patients who require immediate reversal of VKA anticoagulation because of severe or life-threatening bleeding or the need for an emergency procedure, reversal is indicated. Preference is placed on the use of rapid-acting and reliable agents, such as prothrombin complex concentrate or its activated form. Addition of vitamin K can be considered on an individual basis. Specific antidotes are available to reverse the effects of dabigatran (idarucizumab) and the oral anti-Xa agents (andexanet alfa) respectively.

**Recommendation-Specific Supportive Text**

1. Four-factor prothrombin complex concentrate includes factors II, VII, IX, and X. Onset of effect is within 5 to 15 minutes, and duration of effect is 12 to 24 hours. It is a more specific and reliable reversal agent than fresh frozen plasma.

2. Vitamin K is a cofactor for hepatic production of factors II, VII, IX, and X. Onset of effect depends on the route of administration (intravenous versus oral), and the dose given should be predicated on the presence of active bleeding, the maintenance dose of the VKA, the magnitude of INR elevation, and the desired range into which to reduce the INR.

3. A 10-mg intravenous dose is recommended for life-threatening bleeding when there is no concern for restarting the VKA within the next week.

4. Idarucizumab (two, 2.5-mg bolus infusions no more than 15 minutes apart) is indicated to reverse the effect of dabigatran when clinically indicated. Andexanet alfa (bolus and 2-hour infusion, with the dose dependent on the timing of exposure and the individual agent) is used to reverse the effect of the oral anti-Xa agents. Experience with these agents is accumulating.

5. Prothrombin complex concentrate (or its activated form) has also been used with direct oral anticoagulant–related bleeding.

**11.5. Thromboembolic Events With Prosthetic Valves**

**Synopsis**

For patients with a mechanical valve who suffer an embolic event, it is important to assess the adequacy...
Recommendation-Specific Supportive Text

1. There are no comparative-effectiveness trials from which to assess the relative utility of higher-intensity VKA therapy versus standard VKA therapy plus low-dose aspirin in mechanical valve recipients who have experienced stroke or systemic embolism while in target INR range. Excluding the common clinical occurrence of extended time in a subtherapeutic INR range is the first priority. Assessment of medication adherence, intercurrent illness, new or recently adjusted medications, dietary changes, and alcohol intake is critical. Whether to intensify VKA therapy or add low-dose aspirin is a patient-specific, shared decision-making proposition that must weigh several factors, including bleeding risk.

2. The approach to management of the patient with a systemic embolic event and a mechanical mitral prosthesis includes review of INR levels to ensure the patient is in the target INR range most of the time. INR levels may have been subtherapeutic because of suboptimal medication adherence, intercurrent illness, new or recently adjusted medications, dietary changes, or alcohol intake. Whether to intensify VKA therapy or add low-dose aspirin is a patient-specific, shared decision-making proposition that must weigh several factors, including bleeding risk.

3. In those patients with a bioprosthetic valve who have a stroke or embolic event, further imaging with TEE or 3D CT scanning may show leaflet thrombosis, which should respond to anticoagulation with either a VKA or a NOAC. The effectiveness of anticoagulation in aortic and mitral bioprosthetic valve recipients in whom leaflet thrombosis cannot be established as the cause of thromboembolism is uncertain, and patients should undergo a full neurological evaluation to rule out other causes of the neurological event. Shared decision-making that accounts for bleeding risk is a central feature of management.

Synopsis

Mechanical valve thrombosis is typically a subacute to acute event resulting in rapid valve dysfunction because of abnormal or absent motion of the valve leaflets, which often is associated with inadequate VKA anticoagulation. However, recurrent valve thrombosis can be associated with pannus ingrowth in the chronic setting. Mechanical valve thrombosis can present with rapid onset of symptoms or acute pulmonary edema. Physical examination may demonstrate a stenotic murmur and muffled closing clicks, and further urgent diagnostic evaluation is required. The annual rate of prosthetic valve thrombosis with mechanical valves ranges from 0.1% to 5.7%. Higher rates of mechanical valve thrombosis are seen for some specific valve types, within the first 3 months after valve implantation and, for mechanical valves implanted in the mitral or tricuspid position compared with the aortic position.

Recommendation-Specific Supportive Text

1. Mechanical prosthetic valve thrombosis is diagnosed by an abnormally elevated velocity or gradient across the prosthesis, with either limited leaflet motion or attached mobile densities consistent with thrombus, or both. Prosthetic valve obstruction is usually defined as a mean transvalvular gradient increase >50% (or an increase >10 mm Hg across an aortic prosthesis) compared with baseline, after exclusion of other causes, such as a high-output state. When mechanical valve thrombosis is suspected, imaging and Doppler data from TTE provide information on valve function, estimated pulmonary pressures, and LV size and systolic function. Leaflet motion should be visualized with CT or TEE (particularly for a mitral prosthesis) or fluoroscopy (for an aortic prosthesis). Prolonged periods of observation under fluoroscopy or TEE may be required to diagnose intermittent obstruction. The presence and quantification of thrombus and pannus should be evaluated by either TEE or CT.
11.6.2. Intervention

**Recommendation for Intervention for Mechanical Prosthetic Valve Thrombosis**

Referenced studies that support the recommendation are summarized in Table 23.

<table>
<thead>
<tr>
<th>COR</th>
<th>LOE</th>
<th>Recommendation</th>

</thead>
<tbody>
<tr>
<td>1</td>
<td>B-NR</td>
<td>1. For patients with a thrombosed left-sided mechanical prosthetic heart valve who present with symptoms of valve obstruction, urgent initial treatment with either slow-infusion, low-dose fibrinolytic therapy or emergency surgery is recommended.⁹⁻¹²</td>
</tr>
</tbody>
</table>

**Synopsis**

Patients presenting with a thrombosed mechanical valve require urgent therapy. The 2 options of low-dose, continuous-infusion thrombolytic therapy or emergency surgery are both effective, with the decision to proceed with either one based on multiple clinical factors and local experience and expertise.

**Recommendation-Specific Supportive Text**

1. The decision between surgery and systemic fibrinolysis for symptomatic left-sided mechanical valve thrombosis should be individualized (Table 23) after review by the heart valve team, while engaging the patient in a process of shared decision-making and accounting for local experience and expertise. The overall 30-day mortality rate with surgery is 10% to 15%, with a lower mortality rate of <5% in patients with NYHA class I or II symptoms.³⁻⁷ Recent studies using an echocardiogram-guided, slow-infusion, low-dose fibrinolytic protocol have shown hemodynamic success rates >90%, with embolic event rates <2% and major bleeding rates <2%.¹³ Systemic fibrinolysis is therefore an acceptable alternative to reoperation in patients at high or prohibitive surgical risk and in patients who have a small thrombus burden, mild HF symptoms (NYHA class I or II), and low bleeding risk. Absence of surgical expertise should be considered in the clinical decision-making process as a factor that favors thrombolytics, whereas recurrent valve thrombosis favors a surgical approach (Table 23).

11.7. Bioprosthetic Valve Thrombosis

11.7.1. Diagnosis of Bioprosthetic Valve Thrombosis

**Recommendation for Diagnosis of Bioprosthetic Valve Thrombosis**

Referenced studies that support the recommendation are summarized in Table 23.

<table>

</thead>
<tbody>
<tr>
<td>2a</td>
<td>C-LD</td>
<td>1. In patients with suspected bioprosthetic valve thrombosis, 3D TEE or 4D CT imaging can be useful to rule out leaflet thrombosis.¹⁻⁴</td>
</tr>
</tbody>
</table>

**Synopsis**

Bioprosthetic valve thrombosis is most common in the first 3 months after implantation but also has been described in patients years (typically 1 or 2) after valve implantation, with the longest interval being 6.5 years.⁶ Bioprosthetic valves are less thrombogenic than their mechanical counterparts. However, the diagnosis of subclinical bioprosthetic valve thrombosis has increased with use of CT imaging and as a function of the increased numbers of implanted bioprosthetic valves, including TAVI.¹⁻⁵

**Recommendation-Specific Supportive Text**

1. Bioprosthetic valve thrombosis appears to be more common with transcatheter than with surgical bioprosthetic valves. Leaflet thrombosis often is suspected on the basis of an increased transvalvular velocity on routine echocardiographic monitoring and can be confirmed by the finding of hypoattenuation of the valve leaflets on CMR imaging. When there is clinical evidence of stenosis, 3D TEE or 4D CT imaging may be useful to detect a layer of valve thrombus, which may respond to treatment with oral anticoagulation.

11.7.2. Medical Therapy

**Recommendation for Medical Therapy**

<td>B-NR</td>
<td>1. In patients with suspected or confirmed bioprosthetic valve thrombosis who are hemodynamically stable and have no contraindications to anticoagulation, initial treatment with a VKA is reasonable.¹⁻⁴</td>
</tr>
</tbody>
</table>

**Synopsis**

Patients with an obstructed bioprosthesis may have a thin layer of thrombus causing reduced leaflet motion. VKA treatment may result in resolution of the thrombus and improvement in valve function.

**Recommendation-Specific Supportive Text**

1. Multiple small nonrandomized studies support the use of VKAs to treat patients with clinical and subclinical bioprosthetic valve thrombosis after both SAVR and TAVI.¹⁻³,⁴,⁶,⁷ VKA anticoagulation can result in a significant reduction of transvalvular gradient, improved leaflet motion, and clinical improvement.⁴,⁶,⁸
Prosthetic valve stenosis can occur with both mechanical and bioprosthetic valves. Echocardiographic definitions of stenosis severity have been provided by the American Society of Echocardiography. Obstruction of a mechanical valve may be caused by thrombus formation that leads to abnormal leaflet mobility, pannus ingrowth, or a combination of the two. Bioprosthetic valve stenosis may be caused by structural valve deterioration, with leaflet degeneration by thickening, calcification, or tear as the end stage of a slowly progressive process resulting in abnormal leaflet motion, or it may be attributable to other structural causes, including stent creep. Bioprosthetic valve stenosis may also be attributable to nonstructural causes, such as endocarditis, leaflet thrombus, or pannus. The progressive stages are defined by the Valve Academic Research Consortium criteria.9

### Recommendation-Specific Supportive Text

1. TTE and TEE assessment can appropriately detect and quantify prosthetic valve stenosis. TTE within 3 months after valve implantation is useful to provide baseline data on valve hemodynamics and ventricular function. In some patients, the orifice area of the implanted prosthesis may be inadequate to meet the cardiac output demands of the patient, even when the prosthetic valve itself is functioning normally. This circumstance, termed patient–prosthesis mismatch, is associated with a high transvalvular gradient, persistent LV hypertrophy, and an increased rate of cardiac events after valve replacement.

Diagnosis in the setting of bileaflet mechanical valves is complicated by nonlaminar patterns of blood flow, for which significant pressure recovery may be present; thus, a high velocity in the central narrow slit-like orifice may not correlate with prosthetic valve stenosis or patient–prosthesis mismatch. Prosthetic valve stenosis is distinguished from patient–prosthesis mismatch by comparison with the early postoperative baseline study and by visualization of the appearance and motion of the valve leaflets. Prosthetic valve stenosis is characterized by a clinical course of progressive increase in transvalvular velocity and pressure gradient in conjunction with abnormal thickened/calcified leaflets (for bioprosthetic valves) or evidence of pannus formation (with mechanical valves).

2. The motion of the leaflets of a mechanical valve is best evaluated radiographically with fluoroscopy or cine-CT imaging because strong reflections from the mechanical valve obscure motion on echocardiographic imaging in most patients, particularly as assessed on images from the transthoracic approach. With fluoroscopic imaging, the angle of imaging must be adjusted to demonstrate leaflet motion from a side view, permitting measurement of the angles of opening and closure that can be compared with expected values for that valve type. Cine-CT images are obtained at a high frame rate focused on the prosthetic valve in a 3D acquisition. Compared with fluoroscopy, cine-CT 3D images are less operator dependent for measuring opening and closing angles. In addition, cine-CT allows detection of pannus or thrombus on or adjacent

**Synopsis**

Prosthetic valve stenosis can occur with both mechanical and bioprosthetic valves. Echocardiographic definitions of stenosis severity have been provided by the American Society of Echocardiography. Obstruction of a mechanical valve may be caused by thrombus formation that leads to abnormal leaflet mobility, pannus ingrowth, or a combination of the two. Bioprosthetic valve stenosis may be caused by structural valve deterioration, with leaflet degeneration by thickening, calcification, or tear as the end stage of a slowly progressive process resulting in abnormal leaflet motion, or it may be attributable to other structural causes, including stent creep. Bioprosthetic valve stenosis may also be attributable to nonstructural causes, such as endocarditis, leaflet thrombus, or pannus. The progressive stages are defined by the Valve Academic Research Consortium criteria.9

#### 11.8.1.2. Therapeutic Management of Prosthetic Valve Stenosis

**Recommendation-Specific Supportive Text**

1. TTE and TEE assessment can appropriately detect and quantify prosthetic valve stenosis. TTE within 3 months after valve implantation is useful to provide baseline data on valve hemodynamics and ventricular function. In some patients, the orifice area of the implanted prosthesis may be inadequate to meet the cardiac output demands of the patient, even when the prosthetic valve itself is functioning normally. This circumstance, termed patient–prosthesis mismatch, is associated with a high transvalvular gradient, persistent LV hypertrophy, and an increased rate of cardiac events after valve replacement.

Diagnosis in the setting of bileaflet mechanical valves is complicated by nonlaminar patterns of blood flow, for which significant pressure recovery may be present; thus, a high velocity in the central narrow slit-like orifice may not correlate with prosthetic valve stenosis or patient–prosthesis mismatch. Prosthetic valve stenosis is distinguished from patient–prosthesis mismatch by comparison with the early postoperative baseline study and by visualization of the appearance and motion of the valve leaflets. Prosthetic valve stenosis is characterized by a clinical course of progressive increase in transvalvular velocity and pressure gradient in conjunction with abnormal thickened/calcified leaflets (for bioprosthetic valves) or evidence of pannus formation (with mechanical valves).

2. The motion of the leaflets of a mechanical valve is best evaluated radiographically with fluoroscopy or cine-CT imaging because strong reflections from the mechanical valve obscure motion on echocardiographic imaging in most patients, particularly as assessed on images from the transthoracic approach. With fluoroscopic imaging, the angle of imaging must be adjusted to demonstrate leaflet motion from a side view, permitting measurement of the angles of opening and closure that can be compared with expected values for that valve type. Cine-CT images are obtained at a high frame rate focused on the prosthetic valve in a 3D acquisition. Compared with fluoroscopy, cine-CT 3D images are less operator dependent for measuring opening and closing angles. In addition, cine-CT allows detection of pannus or thrombus on or adjacent
to the valve, which is not possible with fluoroscopy. When excessive gradients are present with normal leaflet motion and no thrombus, either patient–prosthesis mismatch or pannus formation is present (or both).

3. Stenosis of a bioprosthesis may occur because of progressive structural valve degeneration or pannus formation. However, stenosis can also occur because of a thin layer of thrombus on the valve cusps, which is reversible with oral anticoagulation therapy. Bioprosthetic valves are less thrombogenic than their mechanical counterparts. However, the diagnosis of subclinical bioprosthetic valve thrombosis has increased with the use of CT imaging and as a function of the increased numbers of implanted bioprosthetic valves, including TAVI.3–7 When there is clinical evidence of bioprosthetic valve stenosis, 3D TEE or 4D CT imaging may be useful to detect a layer of valve thrombus as the cause of the obstruction.

Synopsis

Cumulative survival rates are higher with reoperative AVR than with transcatheter ViV treatment for prosthetic valve stenosis, and a surgical approach is associated with a reduced incidence of patient–prosthesis mismatch, reduced incidence of paravalvular leak, and lower aortic valve gradients.14 The VIVID (Valve-In-Valve International Data) registry examined outcomes with ViV treatment of 459 patients, of whom 40% had isolated stenosis and 30% had mixed lesions.4 Within 1 month after the ViV procedure, 7.6% of patients died and 1.7% had a major stroke. Of the survivors, 93% experienced good functional status (NYHA class I or II), with an overall 1-year survival rate of 83.2%.4 Some systematic reviews comparing outcomes of transcatheter ViV with those of repeat SAVR suggest that hemodynamic outcomes are similar, but stroke and bleeding risks are lower with ViV.15 There is a subset of patients with bioprosthetic valve stenosis attributable to thrombus on the leaflets who may respond to oral anticoagulation with a VKA (Figure 14).6–13

Recommendation-Specific Supportive Text

1. Reoperative surgery for prosthetic valve stenosis is associated with acceptable mortality and morbidity rates in the current era, but the risks are typically higher than those estimated at the time of initial surgery because of older patient age, clinical status at the time of intervention, and reoperative status.2,16 The decision to proceed with surgical versus transcatheter intervention is based on available expertise, individual patient and valve characteristics, and shared decision-making.

2. Catheter-based therapy with transcatheter ViV has emerged as an acceptable alternative to reoperative surgery for the treatment of high- and prohibitive–surgical risk patients with bioprosthetic AS.4,5 Although coronary artery obstruction is more common with aortic ViV procedures than with TAVI for native AS, rates of paravalvular leak and permanent pacemaker implantation are lower with aortic ViV procedures than with TAVI for native AS. Annulus rupture has not been reported. Transcatheter ViV also has been successfully performed for failed surgical bioprostheses in the mitral, pulmonic, and tricuspid positions, although LV outflow obstruction may occur after mitral ViV implantation.

3. A subset of patients presents with stenosis of a bioprosthetic valve attributable to leaflet thrombosis that results in decreased mobility of the leaflets. Leaflet thrombosis can occur from 1 month to years after implantation. If the patient is stable and has no contraindication to long-term anticoagulation, a trial of oral anticoagulation with VKA may result in resolution of the thrombus and improvement in hemodynamics.6–13 However, these patients are at increased risk of recurrent thrombosis (if the anticoagulation is stopped) and early structural deterioration, and thus they require close follow-up.17

11.9. Prosthetic Valve Regurgitation

Regurgitation in a mechanical prosthetic valve may be transvalvular, caused by impaired motion of the valve disk secondary to pannus, thrombus, or vegetation interfering with complete closure of the valve occluders, or paravalvular, caused by suture line disruption related to technical error at implantation, suture failure, annular disruption, or endocarditis. Patients with severe mitral annular calcification are particularly vulnerable to developing late paravalvular leak. Regurgitation in bioprosthetic valves may be paravalvular but more often is
transvalvar, caused by leaflet immobility secondary to calcification or leaflet perforation or flail associated with areas of focal calcification. Echocardiographic definitions of prosthetic valve regurgitation severity have been published by the American Society of Echocardiography.

11.9.1. Diagnosis of Prosthetic Valve Regurgitation

**Synopsis**

The clinical presentation of prosthetic valve regurgitation varies depending on its severity, hemodynamic effects, and etiology. In asymptomatic patients, prosthetic valve regurgitation may be found incidentally on routine clinical or imaging follow-up. A change in auscultatory findings (e.g., change in prosthetic valve sounds or a new murmur) should prompt suspicion of prosthetic valve dysfunction. Symptomatic patients with prosthetic valve regurgitation present with unexplained or new-onset HF or significant hemolysis with or without anemia. TTE is inadequate for evaluation of prosthetic mitral valves; TEE is needed when prosthetic MR is a concern. A critical step in evaluation of the patient with prosthetic valve regurgitation is to distinguish transvalvar from paravalvular leak, which also requires TEE in addition to TTE.
Recommendation-Specific Supportive Text

1. Echocardiography is the primary imaging modality to assess the location and quantify the severity of prosthetic valve regurgitation, often requiring both TTE and TEE approaches.\(^1\)\(^2\) Although TTE provides superior assessment of transvalvular gradients, chamber sizes, and function, TEE is better suited to identify the cause and location of regurgitation and is essential for prosthetic mitral valve because of acoustic shadowing on TTE. Even with prosthetic aortic valves, acoustic shadowing may affect detection of a paravalvular leak by either TTE or TEE, with TTE being suboptimal to assess posterior paravalvular leak and TEE suboptimal to assess anterior defects.\(^3\) The Valve Academic Research Consortium (VARC) has suggested an approach for assessment of paravalvular leak severity and constructed a 5-class grading scheme.\(^7\)

2. 3D echocardiography plays a significant role in determining the precise location and size of the paravalvular leak in patients undergoing intervention. For a successful transcatheter paravalvular leak closure, adequate paravalvular leak assessment includes 1) precise location of the defect(s), 2) precise dimensions, 3) orientation of the defect in relation to the sewing ring and prosthetic valve occluders or leaflets, and 4) location and orientation of the subvalvular structures. Real-time 3D TEE allows optimal visualization of the defects and direct guidance for catheter movement and positioning of the implanted device(s) during the transcatheter closure procedure.\(^4\)\(^5\) 3D TEE also allows assessment of residual regurgitation after device placement. Limitations of 3D TEE include artifacts of ultrasound imaging (eg, dropout, acoustic shadowing, reverberation artifacts) and reduced temporal and spatial resolution.\(^8\) Transcatheter closure using intracardiac echocardiography guidance is possible and alleviates the need for conscious sedation or anesthesia but allows only 2D and color Doppler imaging.\(^9\)

11.9.2. Medical Therapy

Medical therapy for prosthetic valve regurgitation is appropriate in asymptomatic patients or when the cause of regurgitation is valve thrombosis (see Sections 11.6 and 11.8) or prosthetic valve endocarditis (see Section 12.3), although further intervention may ultimately be needed in many of these patients. Some patients tolerate asymptomatic prosthetic valve regurgitation for many years, similar to patients with native valve regurgitation. However, there may be patients who develop rapid progression of the severity of bioprosthetic valve regurgitation because of leaflet degeneration. In patients with hemolytic anemia attributable to paravalvular regurgitation, medical management with folic acid and iron supplementation or periodic transfusion may be possible when the anemia is not severe, with intervention reserved for patients with symptomatic intractable anemia (see Section 11.8.3).

</tbody>
</table>

Synopsis

Prosthetic valve degeneration can result in regurgitation attributable to leaflet calcification and noncoaptation or leaflet degeneration with a tear or perforation. Acute or chronic severe regurgitation may result in HF symptoms and signs. Paravalvular leak may result in hemolysis with symptoms attributable to anemia and HF. New paravalvular leak late after valve implantation raises the concern for IE, which should be excluded because the presence of infection would require antibiotic treatment before surgical therapy and would be a contraindication to transcatheter therapy. Symptomatic patients with paravalvular leak around a prosthetic valve are best managed by surgery, with percutaneous closure of the leak if the patient is at high or prohibitive surgical risk. Symptomatic patients with bioprosthetic valve regurgitation are best managed by surgery, with a transcatheter V/V procedure if the patient is at high or prohibitive risk. Because of rapid progression of bioprosthetic regurgitation, replacement of a leaking bioprosthesis may be considered even in the asymptomatic patient.

Recommendation-Specific Supportive Text

1. Surgery is a viable therapeutic option in many patients with symptomatic paravalvular leak and is associated with reasonable outcomes.\(^1\) The risks associated with surgical intervention depend on the procedure required, be it suture repair or...
repeat AVR. Although surgical reoperation is associated with acceptable mortality and morbidity rates in the current era, it still carries a higher risk than the initial surgery. Kaneko and colleagues examined a cohort of 3380 patients from the STS database (2011–2013) who underwent elective isolated reoperative AVR, and they demonstrated a higher (but acceptable) operative mortality rate than that seen with initial AVR (4.6% versus 2.2%; \( P < 0.0001 \)) and relatively low complication rates.\(^5\) This was true even among octogenarians who underwent reoperative AVR.\(^3\) In a cohort of 136 consecutive patients who underwent surgical correction for a non–endocarditis-related aortic or mitral paravalvular leak (1986–2001), surgical correction of the paravalvular leak was associated with acceptable operative mortality (6.6%) and morbidity rates.\(^1\) More recently, Shah and colleagues reported an operative mortality rate of 3% among 495 patients undergoing surgery for paravalvular leak,\(^14\) with higher risk associated with mitral than with aortic valve procedures (odds ratio: 1.66; 95% CI: 1.25–2.20). These findings are consistent with the findings of Bouhout and colleagues,\(^15\) who reported operative mortality rates of 8% among mitral valve, 3% among aortic valve, and 14% among double-valve patients in a total cohort of 190 patients undergoing surgery indicated for paravalvular leak. Estimates of operative risk for individual patients can be calculated by using the STS risk calculator (http://riskcalc.sts.org/stswebriskcalc/).\(^16\)

2. Prosthetic valve deterioration can result in regurgitation attributable to leaflet calcification and noncoaptation or leaflet degeneration with a tear or perforation. Even in asymptomatic patients with severe prosthetic regurgitation, valve replacement is reasonable because of the risk of sudden clinical deterioration if further leaflet tearing occurs. IE should be excluded or concurrently treated. If a “watchful waiting” approach is taken in asymptomatic patients with severe prosthetic valve regurgitation, referral to a Comprehensive Heart Valve Center is prudent.

3. In some patients, operative risk is high, or surgery is not feasible. Nonrandomized studies have demonstrated clinical success with percutaneous paravalvular leak closure performed by expert operators under the supervision of an MDT at a Comprehensive Valve Center. Procedural success rates for percutaneous paravalvular leak closure, typically defined by no more than mild residual regurgitation and the absence of death and major complications, are highly variable. In a large single-center cohort, percutaneous repair of 141 paravalvular defects was attempted in 115 patients, with an achieved overall success rate of 77% and a 30-day complication rate of 8.7%.\(^6\) In another study of 126 patients who underwent percutaneous paravalvular leak repair, Sorajja and colleagues reported a 3-year survival rate of 64.3%.\(^5\) The degree of residual regurgitation affects symptom improvement and survival. In a cohort of 231 consecutive patients (2006–2017) who underwent percutaneous mitral paravalvular leak closure, the reduction of paravalvular leak to mild or less was achieved in 70% of patients.\(^7,8\) Those patients with mild or less residual paravalvular leak had a survival rate at 3 years of 61%, compared with a rate of 47% in patients with greater degrees of residual paravalvular leak (\( P = 0.002 \)).\(^7,8\) Notably, treatment of HF symptoms with paravalvular leak closure is more successful than is treatment of hemolysis. IE should be excluded before attempted paravalvular leak repair.

4. The Valve-In-Valve International Data registry examined outcomes of transcatheter ViV procedures in 459 patients, of whom about 30% had isolated regurgitation and 30% had mixed lesions.\(^10\) Within 1 month after the ViV procedure, 7.6% of patients died, 1.7% had a major stroke, and 93% of survivors experienced good functional status. The 1-year survival rate was 83.2%.\(^10\) Several systematic reviews have compared outcomes of transcatheter ViV with those of reoperative SAVR. In 1 report, ViV had similar hemodynamic outcomes to repeat surgery and lower stroke risk and bleeding risk than repeat surgery.\(^11\) A meta-analysis of 498 patients demonstrated no significant differences in early and mid-term all-cause mortality rates with ViV or reoperation.\(^17\) In another meta-analysis of 342 patients, reoperative AVR was compared with transcatheter ViV for failed degenerated aortic bioprosthesis and the group undergoing reoperative AVR had a lower all cause mortality with superior hemodynamic outcomes.\(^18\) Thus, although transcatheter ViV appears to be a safe and feasible alternative to repeat SAVR in patients who are inoperable or at high surgical risk, repeat SAVR should remain the standard of care, particularly in low-risk patients.\(^18\)

12. INFECTIVE ENDOCARDITIS

12.1. Classification of Endocarditis

Endocarditis is classified according to whether a native or prosthetic valve is affected and by timing of infection after valve intervention. Prevention of endocarditis is important in all patients with valve disease, both before and after valve replacement or intervention (see Section 2.4.2). The risk factors involved with IE and the predominating causative organisms have evolved over
time, with a recent increased incidence of drug use–associated IE. IE is fatal unless treated appropriately, and there are no asymptomatic patients with endocarditis. The in-hospital mortality rate for IE is 15% to 20%, with a 1-year mortality rate approaching 40%. Noninfective types of endocarditis are not addressed in these guidelines.

12.2. Diagnosis of IE

Synopsis

In patients with suspected endocarditis, the Modified Duke Criteria (Tables 24 and 25) are the current standard for diagnosis and incorporate clinical, imaging, and bacteriological criteria. These criteria have been well validated by comparison with surgical or autopsy findings and in the clinical outcomes of numerous studies involving a wide spectrum of patients, including children, the elderly, prosthetic valve recipients, injection drug users, and non–drug users, as well as patients in both primary- and tertiary-care settings. For patients with VHD and known or suspected IE, obtaining blood culture results before initiation of antibiotic therapy is critical. For diagnosis and management of patients with IE, additional members of the Heart Valve MDT include infectious disease experts, who can provide advanced approaches to microbiological diagnosis. Cardiac imaging with TTE, TEE, and now CT and CT/PET imaging is critical for diagnosis of IE.

Recommendation-Specific Supportive Text

1. Blood culture results are positive in 90% of patients with IE provided that ≥2 blood culture samples are obtained at different times, ideally ≥6 hours apart if clinical status allows, at peripheral sites before initiation of antimicrobial therapy. More important than the time interval of the collection of culture samples is observing strict aseptic technique, avoiding sampling from intravascular lines, and ensuring an adequate volume of blood for the culture sample. Routine incubation of blood culture samples for >7 days is no longer necessary in the era of continuous-monitoring blood culture.
2. The recent onset of new or increased left-sided valvular regurgitation, detected by the presence of a new or louder murmur followed by TTE confirmation, may be attributable to endocarditis, so it is prudent to obtain blood culture samples to exclude this diagnosis.

3. The Modified Duke Criteria (Tables 24 and 25) have been well validated by comparison with surgical or autopsy findings and in the clinical outcomes of numerous studies involving a wide spectrum of patients, including children, the elderly, prosthetic valve recipients, injection drug users, and non–drug users, as well as patients in both primary- and tertiary-care settings. About three-fourths of patients with IE are diagnosed within 30 days of the onset of infection, so classic clinical features of IE, such as embolic or vasculitic skin lesions, renal disease caused by immune complex deposition, and immunologic abnormalities, are often absent. In these cases, maintaining a high level of clinical suspicion with regard to the possibility of IE in patients who are susceptible is paramount.4,6–10

4. The diagnosis of IE can still be difficult and is frequently delayed, which may cause progressive and potentially irreversible structural damage to the heart and other organ systems secondary to vascular–embolic and immunologically mediated events. Additionally, stroke (16.9%), embolization other than stroke (22.6%), HF (32.3%), intracardiac abscess (14.4%), and the need for surgical therapy (48.2%) remain common. Patients with suspected IE are most optimally managed in an environment that coordinates the management of specialists who are well attuned to the various organ systems, pathological processes, and potential treatment systems and non–culture-based technology. In the 10% of patients with culture-negative endocarditis, serological testing or advanced laboratory diagnostics (eg, polymerase chain reaction) may be helpful to identify the etiologic agent.1,42,75–78
modalities involved, ideally at centers with immediate access to cardiac surgery during the initial observation stages of the disease. With the emerging use of telemedicine, it may be reasonable to manage patients with lower-acuity IE in a center without on-site multispecialty care by telecommunication with a Heart Valve MDT and infectious disease specialists, with rapid transfer of the patient to a Comprehensive Valve Center if needed.11-13

5. The presence of valvular vegetation is a major criterion in the diagnosis of IE. TTE has a sensitivity between 50% and 90% and a specificity >90% for detection of vegetations in native valve endocarditis. TTE has a sensitivity of only 36% to 69% in prosthetic valve endocarditis, but TTE still has a role in these patients for detection and quantitation of valve dysfunction (even in the challenging situation of regurgitation in the mechanical prosthetic mitral valve, for which a proximal convergence zone may provide important evidence for a paravalvular leak), evaluation of ventricular size and systolic function, and estimation of pulmonary pressures. TTE exhibits superior imaging over TEE for the anterior aspect of a prosthetic aortic valve, which is commonly shadowed by the valve on TEE. TTE also allows measurement of aortic transvalvular velocity/ gradient, which is not always possible on TEE. Although TTE will not definitively exclude vegetations or abscesses in IE, it can identify very high-risk patients, establish the diagnosis, and guide early treatment decisions (Figure 8).14,19-23

6. The sensitivity of TEE in native valve endocarditis ranges from 90% to 100%, with sensitivity ranges slightly lower in prosthetic valve endocarditis. TEE is superior to TTE in the visualization of both vegetations and paravalvular complications, which can be anatomic (eg, valve perforation, abscesses, and pericardial effusion) or hemodynamic (eg, valve regurgitation, fistulae, and intracardiac thrombi) in nature. TTE and TEE are complementary for the comprehensive evaluation of hemodynamics and anatomy in patients with IE. TEE should be used as an adjunct in patients with echocardiographic features of IE on TTE to rule out the presence of findings such as abscesses, which may alter the therapeutic approach to the management of the patient. TEE also serves a vital role in reassessment of patients with known IE with suspected clinical complications, as well as a guiding tool in the intraoperative assessment and management of the patient with IE. The timing of repeat examinations depends on the clinical presentation and course and on the virulence of the microorganism. Increasing vegetation size under therapy must be considered a risk factor for new embolic events, whereas unchanged or reduced vegetation size under therapy may be more difficult to interpret.23,29,32-40

7. HF, paravalvular extension, and embolic events represent the 3 most frequent and severe complications of IE. They are also the 3 main indications for early surgery, which is performed in almost 50% of cases. If signs or symptoms consistent with any of these complications exist, there should be a very low threshold for repeat imaging in these patients. TEE may miss initial paravalvular abscesses, particularly when the study is performed early in the patient’s illness. In such cases, the incipient abscess may be seen only as nonspecific paravalvular thickening, which on repeat imaging across several days may become recognizable as it expands and cavitates. Similarly, paravalvular fistulae and pseudoaneurysms develop over time, and negative early TEE images do not exclude the potential for their development. A single negative TEE study cannot rule out underlying IE, and a repeat TEE study should be performed when a suspicion of persistence of infection remains or if complications ensue. Conversely, in the absence of clinical deterioration or new signs and symptoms, routine follow-up echocardiography is probably of only limited clinical utility.24,41,42,44-46

8. Intraoperative TEE during cardiac surgery has an important role in the evaluation and quality control of a large variety of pathologies. Clinical and echocardiographic characteristics may change during an episode of IE because of the prolonged active phase and fluctuating course of this disease. Even if preoperative TEE has been performed, vegetation change/embolization or extension of the infectious process beyond the valve tissue may occur. In addition, other valves may become involved as the disease timeline progresses. Intraoperative TEE has been invaluable for baseline reassessment of anatomical or hemodynamic changes that may occur in the interval between the diagnostic echocardiogram and the time of surgery. TEE is also an important monitoring tool for evaluation of operative complications, such as air emboli, and an important adjunct to ensure the quality of the intended surgical result.39,50

9. The recently published randomized POET (Partial Oral Treatment of Endocarditis) trial studied 400 patients with “stable” left-sided IE caused by streptococcus, Enterococcus faecalis, S. aureus, or coagulase-negative staphylococci. Patients who had been on intravenous antibiotics for at
least 10 days were randomized to continuation of the usual course of intravenous antibiotics or discharge to ambulatory treatment with oral antibiotics. As part of the study protocol, patients were reassessed by TEE within 1 to 3 days of completion of their assigned treatment to confirm that the patient had a sufficient response to therapy. The primary outcome was a composite of all-cause mortality, unplanned cardiac surgery, embolic events, or relapse of bacteremia with the primary pathogen. At 6 months after antibiotic treatment completion, the switch to oral antibiotic therapy was noninferior to traditional long-term intravenous therapy.51

10. IE in patients with *S. aureus* bacteremia frequently involves normal cardiac valves and is seldom accompanied by the physical stigmata of IE, rendering the diagnosis of the disease difficult. Reliance on physical examination findings and clinical stigmata is likely to result in under-diagnosis of *S. aureus* IE in a large number of cases. TEE is cost-effective to guide duration of therapy in patients with intravascular catheter-associated *S. aureus* bacteremia, patients with intracardiac electronic devices, or other patients at higher risk of IE (including those with previous prosthetic valve surgery) or associated complications. Despite early diagnosis and appropriate therapy, IE after *S. aureus* bacteremia is frequently associated with disabling and life-threatening sequelae. The overall mortality rate of *S. aureus* IE ranges from 19% to 65%. Other complications include HF (20%–50%), paravalvular cardiac abscesses (30%–40%), neurological manifestations (30%), and systemic embolization (40%).11,36,55,56

11. When compared with native valve endocarditis, prosthetic valve endocarditis is characterized by a lower incidence of vegetations (especially in mechanical prostheses) and a higher incidence of annular abscess and other paravalvular complications. Because cardiac auscultation may also be less revealing in prosthetic valve endocarditis and because ordinarily less virulent organisms may cause more anatomic destruction before culture or serological detection, early use of TEE in these high-risk patients is important. The sensitivity of TEE for detecting IE is lower with prosthetic valves than with native valves, so the importance of comparing serial echocardiographic studies is paramount to making the diagnosis.59,60

12. Electrocardiographic-synchronized, multidetector-row CT is emerging as an important tool for noninvasive cardiac assessment and may be helpful in evaluating complications of IE. CT may also be indicated in right-sided IE to demonstrate the presence of septic pulmonary infarcts and abscesses. Although CT is less accurate than TTE and TEE for identifying valvular vegetation and valvular perforations, CT is useful for evaluating patients with equivocal findings on TEE and for evaluating complications in patients with suspected paravalvular infection. CT imaging is particularly useful in preoperative evaluation of patients with aortic valve IE to evaluate coronary artery and aortic involvement. In suspected prosthetic valve endocarditis, cardiac CT is less affected by the shadowing of mechanical valves or bioprosthetic valve sewing rings than is ultrasonography. CT also allows evaluation of the motion of mechanical valve occluders and provides visualization of thrombus or infective material limiting valve occluder motion. Additional imaging modalities, such as cardiac valvular fluoroscopy, can be an adjunct to other clinical and imaging information to detect the presence of obstructive disease in mechanical prosthetic valves affected by IE.61,64–68

13. Diagnosis of IE can still be a vexing undertaking. It has been shown that the use of 18F-fluorodeoxyglucose PET/CT at the initial presentation of patients with suspected prosthetic valve endocarditis increases the diagnostic capability of the Modified Duke Criteria. The inclusion of abnormal 18F-fluorodeoxyglucose cardiac uptake as a major criterion addition to the Modified Duke Criteria enabled a recategorization of 76% of patients with prosthetic valve endocarditis initially classified as “possible” IE on admission to the hospital to “definite” IE. This tool must be used in centers with great experience with the technology, as this imaging technique may also be prone to false-positive results because of sterile inflammation in implanted prosthetic valves. 18F-fluorodeoxyglucose PET/CT may also be considered a complementary diagnostic tool for some patients with suspected native valve endocarditis.69–71

14. Because the frequency of IE among patients with *S. aureus* bacteremia is reported to be approximately 30%, with many cases not being clinically suspected, TEE may be considered in the setting of *S. aureus* bacteremia to rule out IE. Even in *S. aureus* bacteremia from a known extracardiac source, such as an infected joint or joint prosthesis, TEE might be considered, given known cases of seeding of valve tissue in this type of setting. Possible exceptions are patients who have no underlying cardiac predisposing conditions or clinical signs of IE whose fever and bacteremia resolve within 72 hours after removal of a likely
infected focus (such as intravascular catheter removal). In the absence of 1) prolonged bacteremia lasting >4 days, 2) a permanent intracardiac device, 3) hemodialysis dependency, or 4) spinal infection or nonvertebral osteomyelitis, the risk of IE is relatively low, and routine TEE may not be necessary.22,53,54,74

Synopsis

Details of specific antimicrobial regimens have been published previously by the AHA, European Society of Cardiology, and British Society for Antimicrobial Chemotherapy and are not repeated in this guideline. In patients on anticoagulant therapy for AF or a mechanical heart valve, continued anticoagulation is associated with a higher risk of intracranial bleeding, particularly after an embolic event. In patients with suspected intravenous drug use, effective long-term therapy includes referral to an addiction treatment program. In a select subset of patients with a stable clinical course, it may be possible to convert from intravenous to oral antibiotics if TEE confirms the absence of paravalvular extension of the infection. In addition to antibiotic therapy, early surgical intervention often (approximately 50% of the time) is needed to manage infection and the sequelae of valve leaflet and paravalvular tissue destruction (Figure 15).1,2,37-42

Recommendation-Specific Supportive Text

1. Optimal treatment of IE is based on the appropriately timed initiation of antimicrobial therapy that is effective against the specific infective organism involved. Empirical therapy may be necessary in patients with septic shock or patients who show high-risk signs on presentation. Although no RCTs have been performed with regard to the use of antibiotic therapy in IE, the mortality rate before the antibiotic age neared 100%. Specific antimicrobial regimens, depending on the causative microorganism, have been published by the British Society for Antimicrobial Chemotherapy and the AHA. Because there are continuous changes in antimicrobial sensitivity over time, as well as regional and site-specific differences in antimicrobial susceptibility profiles, concomitant management with the assistance of a consultant thoroughly familiar with these patterns is imperative.1-7

2. Drug use–associated endocarditis is associated with a significantly higher complexity of care, with increased rates of readmission, reinfection, and recurrent need for repeat interventions, and its incidence has risen 12-fold over the past decade. Addiction specialists are an important part of the Heart Valve Team for this patient population. Addiction studies have shown that treatment outcomes for behavioral interventions alone for opioid use disorders are dismal, with >80% of patients returning to drug use. Some data show that patients who used pharmacotherapy, such as agonist therapy (opioid substitution therapy), in addition to behavioral treatments had a 50% reduction in relapse compared with those who used behavioral therapies alone.8-10

3. Stroke in patients with IE can have several mechanisms, including hemorrhagic transformation of an ischemic infarct, septic erosion of an atherosclerotic vessel without aneurysm formation, and rupture of a mycotic aneurysm. Up to 35% of all patients with IE develop clinically evident systemic emboli. If more sensitive tests, such as magnetic resonance imaging, are used, a much higher proportion of patients with IE have evidence of emboli. In these patients, the most common cause of stroke is septic embolus
resulting in ischemia, often followed by hemorrhagic transformation. Anticoagulant therapy may increase the risk of an embolic infarct converting to a hemorrhagic infarct, and this risk must be weighed against the higher risk of recurrent embolization and valve dysfunction, particularly in patients on anticoagulation for a prosthetic valve. A specialist in the field of neurology or neuroradiology should be added to the Heart Valve Team when stroke complicates IE.\textsuperscript{11,18–24}

4. POET randomized stable patients who had left-sided endocarditis caused by streptococcus, \textit{E. faecalis}, \textit{S. aureus}, or coagulase-negative staphylococci to treatment arms of continued intravenous treatment or a switch to oral antibiotic treatment after antibiotics had been administered intravenously for at least 10 days. Within 1 to 3 days before the completion of the assigned antibiotic treatment, TEE was performed to confirm that the patient had a sufficient response to treatment as part of this protocol.\textsuperscript{25}

5. In patients with native valve endocarditis, routine use of VKA is not recommended. In patients on VKA for other indications who have IE, VKA discontinuation should be considered at the initial presentation for several reasons: 1) the risk of bleeding associated with any needed urgent invasive procedures, 2) the risk of hemorrhagic stroke, and 3) the possible need for early surgery, which is required in roughly 50% of patients with prosthetic valve endocarditis. There are no RCTs studying the use of bridging therapy with intravenous or subcutaneous anticoagulant therapy in patients with IE, but observational studies suggest an increased risk of hemorrhagic stroke in patients on intravenous UFH during the acute phase of acute IE. Decisions about continued anticoagulation and antiplatelet therapy should ultimately be directed by the patient’s cardiologist and cardiothoracic surgeon, in consultation with a neurology specialist if neurological findings are clinically present or noted on imaging.\textsuperscript{11,27–34}

6. Two sets of blood culture samples are the minimum for a secure microbiological diagnosis of IE.
Antibiotic therapy is most effective if the identity and sensitivities of the responsible organism are known. *S. aureus* is the most common pathogen responsible for prosthetic valve endocarditis but still accounts for only 23% of cases. The leading cause of “culture-negative IE” is the use of antibiotics before blood cultures are obtained. Negative blood cultures in the setting of IE delay diagnosis and often require additional serological and polymerase chain reaction testing.\textsuperscript{22,35,36}

## Synopsis

Management of patients with IE requires a Heart Valve MDT supplemented by inclusion of infectious disease and neurology specialists. The indications for early surgery for patients with IE include HF, persistent infection, abscess, heart block, infection with highly resistant organisms, or recurrent emboli (with persistent vegetations). In patients with implanted electronic devices, infection of the entire system is likely, even if it appears confined to the leads on imaging, and this mandates removal of the entire system to eradicate the infection. In patients with an indication for early surgery, a cerebral embolic event is not a contraindication unless there is extensive neurological damage or intracranial hemorrhage (Figure 16).

### Recommendation-Specific Supportive Text

1. IE is best managed in an environment with ready access to specialists in the fields of cardiology, cardiothoracic surgery, and infectious disease, with the option for transfer of complicated cases to a Comprehensive Valve Center when needed. A risk-scoring system using the STS database has been developed to predict surgical risk in patients with IE to help better counsel patients and more objectively define the risks associated with surgery. One trial noted that even when surgery is indicated, women were less likely to undergo a surgical procedure than men (26% versus 47%) and that women had higher in-hospital and 1-year mortality rates than men despite similar comorbidities.\textsuperscript{1,2,4–6}
2. Studies have reported a 21% in-hospital mortality rate in patients with IE and HF who were treated with surgery versus a 45% mortality rate in those who were treated medically. In left-heart native valve endocarditis, 4 baseline features have been independently associated with 6-month mortality: 1) abnormal mental status, 2) moderate to severe HF, 3) bacterial etiology other than *Viridans streptococcus*, and 4) medical therapy without valve surgery. Except in injectable drug users, the risk of reinfection after prosthetic valve surgery is low relative to the risk associated with not having surgery in patients with hemodynamic and microbial indications for surgery. Prosthetic valve endocarditis is clearly associated with both higher mortality rates (especially with HF, severe valvular dysfunction, or a staphylococcal or fungal infectious microbe) and higher post-treatment HF-related disability. Surgical series report surgical rates of 50% in patients with prosthetic valve endocarditis, and these patients show improved outcomes over medical therapy, even with controlling for severity of illness at time of diagnosis.⁸⁻¹⁹

3. Compared with patients with IE attributable to other organisms, patients with left-sided *S. aureus* IE were significantly more likely to die (20% versus 12%), experience an embolic event (60% versus 31%), have a central nervous system event (20% versus 13%), and not undergo surgery (26% versus 39%). Staphylococcal prosthetic valve endocarditis has been associated with a mortality rate as high as 70%, which is driven by resistant staphylococcal species. When *Staphylococcus* is the bacteria, death occurs in <5% of patients with right-sided native valve...

---

**Figure 16. Endocarditis treatment.**

Colors correspond to Table 2. *IE caused by streptococcus, E. faecalis, S. aureus, or coagulase-negative staphylococci deemed stable by the Heart Valve Team. Early surgery defined as during initial hospital course and before completion of a full course of appropriate antibiotics. In patients with an indication for surgery and a stroke but no evidence of intracranial hemorrhage or extensive neurological damage, surgery without delay may be considered. DUA indicates drug use associated endocarditis; HF, heart failure; ICD, implantable cardioverter-defibrillator; ID, infectious disease; IE, infective endocarditis; IV, intravenous; NVE, native valve endocarditis; OST, opioid substitution treatment; pt, patient; PVE, prosthetic valve endocarditis; Rx, therapy; S. aureus, *Staphylococcus aureus*; TEE, transesophageal echocardiography; VHD, valvular heart disease; and VKA, vitamin K antagonist.
endocarditis, which is an important distinction in injectable drug users. Certain pathogens, such as Pseudomonas aeruginosa, Brucella, fungi, enterococci, and gram-positive cocci are extremely difficult to cure with medical therapy alone and are also prone to abscess or fistula formation and other cardiac tissue destruction. The mortality rate is also significantly lower in patients treated with antifungal agents combined with surgery than in those treated with antifungal agents alone (42% versus 59%).9,15,20,22,28-35

4. Abscess in native valve endocarditis is a life-threatening complication that cannot be cured with antibiotic therapy alone. Extensive paravalvular infections (including annular or aortic abscesses and destructive penetrating lesions or fistulae) are associated with a mortality rate ≥40% and heart block. The long-term results of surgery are very satisfactory, with an actuarial survival rate of 75%±6% at 5 years. Freedom from recurrent IE has been reported to be 76% at 8 years. Surgical series have shown that the surgical results are related more to a surgeon’s ability to remove all infected tissues and reconstruct functional anatomy than to the type of valve used for a replacement. Patients with prosthetic valve endocarditis complicated by paravalvular invasion, as manifested by intracardiac abscesses, fistulae, or heart block, experience high mortality rates and are rarely cured by medical treatment alone. By contrast, surgical series have reported surgical survival rates of 71% in this high-risk group.9,41-44

5. Blood culture samples will typically become negative after 48 hours of appropriate antimicrobial therapy, except for with methicillin-resistant S. aureus and other resistant organisms, for which it may take up to a week for cultures to become negative. Some caution is advised in patients who develop recurrent fever after an initially successful response to antibiotics because the fever could be explained by reasons other than the endocarditic valve. Ongoing infection despite antibiotic therapy is common with aggressive microorganisms, resulting in abscess formation, valve destruction, fistulae, or large vegetations.7,9,15,46,48

6. Optimal therapy for cardiac device IE combines complete device extraction and a prolonged course of parenteral antibiotics with complete device and lead removal, even if evidence for infection appears to be limited to the generator pocket site. A prospective cohort study using data from the ICE-PCS (International Collaboration on Endocarditis–Prospective Cohort Study) showed that among patients with cardiac device IE, the rates of both concomitant valve infection and mortality are high, particularly if there is valve dysfunction. A proportional hazards regression analysis showed a survival benefit at 1 year for device removal during the initial hospitalization; 28 of 141 patients (19.9%) who underwent device removal during the index hospitalization had died at 1 year, versus 13 of 34 (38.2%) who did not undergo device removal (HR: 0.42; 95% CI: 0.22–0.82).49,54,55,72

7. Relapsing infections may be caused by incomplete sterilization of valvar or paravalvular tissue secondary to a deep tissue infection. Even in the absence of other indications for intervention, such as severe valve dysfunction or a resistant organism, if there is no other source for persistent bacteremia, heart valve infection must be presumed to be the source. If the source of infection is uncertain, additional imaging with PET/CT may be helpful in decision-making.7

8. The incidence of drug use–associated IE continues to rise, with a known risk of IE that is 100-fold higher than that of the general population. In a National Institutes of Health–sponsored statewide health survey in the state of North Carolina, 42% of all IE valve surgeries performed between 2007 and 2017 were undertaken in patients with injection drug use–related IE. The care of these patients is associated with longer hospital stays, higher readmission rates, higher rates of recurrent IE, and higher costs of care. With evolving science in addiction medicine, there is evidence that referral to addiction therapy can reduce mortality and morbidity rates in these patients. In patients admitted with drug use–associated endocarditis, addiction specialists are an integral part of the MDT.56-60

9. Embolic events are associated with increased morbidity and mortality in IE and occur in 20% to 40% of patients with IE. The risk of embolism is highest during the first days after initiation of antibiotic treatment and decreases after 2 weeks. Embolic incidence decreases to 9% to 21% after initiation of antibiotic treatment. Factors associated with a new embolic event are vegetation size >10 mm and marked vegetation mobility (especially when associated with the anterior leaflet of the mitral valve). Early surgery is associated with a reduction in the rate of embolic complications in patients who present with left-sided IE, severe VHD, and large vegetations (>10 mm).53,61,64-66

10. With native valve endocarditis, large vegetation size is associated with a markedly higher rate of embolic phenomena. In an RCT of surgical intervention in patients with severe left-sided valve dysfunction and vegetations >10 mm in

**Synopsis**

To assure the best possible outcome for a woman with VHD and her baby, a comprehensive evaluation is best performed before the time of conception. During pregnancy, the frequency and intensity of follow-up and treatment are heavily dependent on the type and severity of valve lesion, as well as patient symptoms.

**Recommendation-Specific Supportive Text**

1. The risks to the mother and fetus during pregnancy are highly dependent on the type and severity of valve disease. Clinical evaluation of women with VHD who are contemplating pregnancy includes a complete TTE with full anatomic and hemodynamic assessment of the valves. A congenital bicuspid or unicuspoid aortic valve is often associated with dilation of the aortic sinuses, the ascending aorta, or both. Evaluation of women with a congenitally abnormal aortic valve includes assessment of the aorta before pregnancy because of the risk of further aortic enlargement and aortic dissection during pregnancy.

2. Pre-pregnancy counseling with a cardiologist experienced with managing women with valve disease during pregnancy allows discussion of the risks of pregnancy for the mother and fetus. A complete assessment of functional capacity, severity of valve lesions, status of the LV and RV, and pulmonary...
Synopsis

Women with severe VHD are at risk of HF, arrhythmia, and other cardiac disorders during pregnancy. Although pressures is necessary to determine the risk of pregnancy and delivery. Medications are reviewed to avoid agents that may have potential harmful effects on the fetus. Pre-pregnancy evaluation also allows discussion of options for interventions before pregnancy, such as valve replacement, valve repair, or percutaneous aortic or mitral balloon dilation, particularly in those patients with severe rheumatic MS or AS.1–5

3. Women with severe valve disease who become pregnant are at an elevated risk of cardiac morbidity and mortality. Babies born to such mothers are also at risk of serious complications. Identification and management of complications are improved by monitoring in a tertiary-care center with an experienced team of healthcare providers who have expertise in managing high-risk cardiac conditions during pregnancy.1–12

4. Patients with severe valve disease may be asymptomatic, which can pose a diagnostic and therapeutic dilemma in women with these disorders who are considering pregnancy. Exercise testing is reasonable to assist with risk assessment in patients in whom it is unclear whether pregnancy can be tolerated without an intervention to repair or replace the valve before pregnancy.3–5,11–13

Symptoms provoked by exercise testing are synonymous with spontaneous symptoms. Patients who develop symptoms on exercise testing should be treated as having symptomatic valve disease (Stage D), and should undergo pre-pregnancy counseling by a cardiologist with expertise in managing women with VHD during pregnancy.

Recommendation-Specific Supportive Text

1. Beta-blocker medications are used to control heart rate or to treat arrhythmias. However, maternal use of beta blockers has been associated with a newborn birth weight approximately 100 g lower than that of newborns whose mothers did not take beta blockers.6 The use of beta blockers with beta-1 selectivity avoids the beta-2 effects on uterine relaxation. The incidence of fetal growth retardation is lower with metoprolol treatment than with atenolol treatment in pregnancy.1–6

2. Diuretic medications can alleviate the effects of volume overload in pregnant women with VHD and HF symptoms (Stage D). However, reduction of volume overload must be balanced against the reduction in placental blood flow associated with diuretic medications.7,8 Additionally, data from ROPAC suggested that maternal diuretic use was associated with rates of low birth weight and fetal mortality that were higher than for women not taking any medications. In part, this association was attributable to the severity of the underlying HF requiring treatment.7,8

3. ACE inhibitors and ARBs are strongly associated with fetal malformations when used by women during pregnancy.9–11

</tbody>
</table>

**Synopsis**

In women with severe VHD who are considering pregnancy, the indications for considering intervention include the presence of symptoms, asymptomatic severe AS, asymptomatic severe MR with a repairable valve, and asymptomatic severe rheumatic MS with a valve morphology suitable for PMBC. If a prosthetic valve is needed, the shared decision-making process about the choice of type of prosthetic valve should include discussion of the risks of valve thrombosis and adverse effects from anticoagulation with mechanical valves versus the reduced durability of bioprosthetic valves in young women (Figure 17).

**Recommendation-Specific Supportive Text**

1. Standard indications for intervention in symptomatic patients with severe valve disease also apply to women who are considering pregnancy.1,4,11

2. Women of childbearing age who require valve intervention have important choices to make about the risks and benefits of the types of prosthetic valves. The risks to the mother and fetus of valve thrombosis and anticoagulation during pregnancy with a mechanical valve must be weighed against the reduced durability of bioprosthetic valves in young women. For women considering a mechanical prosthesis, it has proposed that they undergo a preoperative trial of anticoagulation with warfarin to assess the dose needed to achieve a target INR. In 1 small study, women who required <5 mg daily of warfarin and then underwent subsequent mechanical AVR did not experience maternal or fetal complications during pregnancy.15 Larger trials are needed, however, before this becomes standard practice. Shared decision-making with a cardiologist with expertise in the management of severe valve disease during pregnancy allows discussion of these issues in women of childbearing age before valve surgery, even when pregnancy is not planned in the near future.1,4,16

3. Severe rheumatic MS presents a significant risk of maternal adverse outcome during pregnancy. In asymptomatic women with severe rheumatic MS (mitral valve area ≤1.5 cm², Stage C) and favorable valve morphology who are considering pregnancy, PMBC results in an increase in mitral valve area and reduction in transmitral gradient, which makes the patient more resilient to the hemodynamic load of pregnancy.1,4,12,13

4. Pregnant women with a bioprosthetic valve, compared with women with a mechanical valve who are on anticoagulation, have a lower risk of valve thrombosis, excessive bleeding, and fetal and maternal death.14 The Ross procedure is an alternative if performed in women with favorable anatomy and at centers with expertise in the procedure.

5. Most patients with mild to moderate AS can tolerate the hemodynamic changes of pregnancy without cardiovascular events. Patients with severe AS are at an increased risk of complications, with HF developing in 10% to 44% of patients and arrhythmias in up to 25%, even if they were asymptomatic before pregnancy. Progressive as well as sudden deterioration may occur during pregnancy and delivery in patients with severe AS. Fetal complications are frequent also. Options for relief of valvular AS in women include percutaneous aortic balloon dilation in patients with noncalcified congenital AS, the Ross procedure, or a surgical bioprosthetic or mechanical valve. TAVI has not been studied in young women, and few data
exist on outcomes with this valve type during pregnancy.\textsuperscript{1,2,6–10}

6. Some women with severe asymptomatic AS, normal LV systolic function, and normal biomarkers may choose to undergo pregnancy without valve intervention. The risks of deterioration during pregnancy must be balanced against the risk of mechanical valve complications during pregnancy or the long-term risks of a bioprosthetic valve in a young patient. In experienced centers, these women can often be treated with activity restriction, volume management, and optimization of loading conditions.\textsuperscript{1,3,6–10}

7. The threshold for valve operation for valve regurgitation is higher in the asymptomatic patient who might ever become pregnant than in patients who will not become pregnant because there always is the possibility that valve repair will not be successful and a prosthetic valve will be needed. Most patients with asymptomatic severe MR tolerate the hemodynamic changes of pregnancy, and there is no evidence for acceleration of LV dysfunction during pregnancy. High-risk features for development of HF during pregnancy in women with MR include depressed LV systolic function and pulmonary hypertension (pulmonary artery systolic pressure $>$50 mm Hg). In high-risk asymptomatic women with severe MR, referral to a Comprehensive Valve Center allows consideration of mitral valve morphology, the likelihood of a successful valve repair, and estimated surgical risk in the decision-making process.\textsuperscript{1,11,16}

### Synopsis

In pregnant women with severe VHD who develop severe, intractable symptoms despite maximal medical therapy, surgical or percutaneous intervention may become necessary.

### Recommendation-Specific Supportive Text

1. Patients with severe AS may develop progressive HF or sudden hemodynamic deterioration during the stress of pregnancy. Both open heart surgery and percutaneous balloon dilation of the aortic valve are high-risk procedures during pregnancy for both the mother and the fetus and should be performed only if there is hemodynamic deterioration or if there are severe NYHA class III or IV HF symptoms. The type of intervention will be dependent on the valve morphology and on the expertise of the center. The intervention should always be performed in a center with a multidisciplinary group of cardiologists, interventionalists, cardiac anesthesiologists, and obstetricians specializing in high-risk obstetrics.1–7,9–12

2. Patients with severe rheumatic MS may develop progressive HF or sudden hemodynamic deterioration during the hemodynamic stress of pregnancy. Percutaneous balloon dilation of the mitral valve is a high-risk procedure during pregnancy for both the mother and the fetus and should be performed only if there is hemodynamic deterioration or if there are severe NYHA class III or IV HF symptoms.17–19 The intervention will also be dependent on an acceptable valve morphology. The intervention should always be performed in a center with a multidisciplinary group of cardiologists, interventionalists, cardiac anesthesiologists, and obstetricians specializing in high-risk obstetrics.1–7,9–12

3. Regurgitant valve lesions are generally better tolerated during pregnancy than are stenotic ones. Valve surgery is reasonable only in the rare pregnant woman with severe valve regurgitation with NYHA class IV HF symptoms refractory to medical therapy.13–16

4. Valve surgery during pregnancy is high risk, with a 30% to 40% fetal mortality rate and up to 9% maternal mortality rate reported. It should be reserved only for patients with severe, intractable symptoms unresponsive to bed rest and maximally tolerated medical therapy.13–16

### Synopsis

Pregnancy in women with mechanical heart valves is very high risk and has been classified by the World Health Organization as Risk Category III (significantly increased risk of maternal mortality or severe morbidity). Contemporary studies and prospective registries of pregnancy in women with mechanical heart valves confirm that maternal risk remains high: Maternal mortality rate is approximately 1%, and the risk of valve thrombosis is approximately 5%.2,5,9 Given the substantial risk of adverse maternal and fetal...
events, there is a need for specialized expertise in the counseling and care of women with prosthetic heart valves who are considering pregnancy or who are pregnant.

**Recommendation-Specific Supportive Text**

1. A preconception TTE is used to assess valve function, ventricular function, and pulmonary artery systolic pressure. Preconception TTE can help identify women with valve dysfunction who may benefit from valve intervention before conception. Results can facilitate patient counseling about specific risks of pregnancy.

2. The management of prosthetic heart valves during pregnancy is substantially different from the management of prosthetic heart valves in a nonpregnant patient. There is a much higher risk of mechanical valve thrombosis during pregnancy because of the hypercoagulable state. Choosing the appropriate anticoagulation strategy to balance risks to the mother and fetus requires a team familiar with management of prosthetic heart valves in pregnancy to provide comprehensive counseling. The management of anticoagulation also requires specialized expertise, and frequent titration of VKA or heparin doses is needed. Transvalvular gradients increase during pregnancy because of increased heart rate, plasma volume, and stroke volume. In the event that valve intervention is required during pregnancy, the comprehensive Heart Valve Team and maternal-fetal medicine team is required to optimize maternal and fetal outcomes.

3. Each anticoagulation strategy has relative advantages and disadvantages in terms of maternal and fetal safety, but there is no anticoagulation strategy that is consistently safe for the mother and fetus. The maternal mortality rate is >1%, and serious maternal and fetal complications are common, even with modern mechanical heart valves and careful management. After counseling, some women with mechanical heart valves may choose not to become pregnant, whereas others may wish to proceed with pregnancy, so comprehensive and candid counseling about the risks of pregnancy with a mechanical heart valve is important.

4. Pregnancy is a time of increased risk of mechanical valve thrombosis, so there should be high suspicion of valve thrombosis in women with an embolic event, clinical deterioration, symptoms of HF, or a pronounced increase in valve gradients or valve regurgitation during pregnancy. TEE is useful to visualize leaflet motion and thrombus burden. Fluoroscopy and gated cardiac CT are also useful in evaluating patients with suspected valve thrombosis.

**13.2.2. Anticoagulation for Pregnant Women With Mechanical Prosthetic Heart Valves**

</tr>
</tbody>
</table>
Synopsis

Pregnant women with mechanical heart valves are at increased risk of serious maternal complications, including valve thrombosis, thromboembolism, hemorrhage, and death. The risk of poor fetal outcomes is also high, with increased rates of spontaneous abortion, fetal death, fetal hemorrhage, and teratogenicity related to VKAs. For women with mechanical heart valves, the maternal mortality rate remains >1%. More than one-third of women with mechanical heart valves have a serious maternal or fetal complication during pregnancy.1–4,9,24,33,34

All women with mechanical heart valves require uninterrupted therapeutic anticoagulation throughout pregnancy. The choice of anticoagulation strategy is challenging because there are inherent trade-offs between maternal safety and fetal safety. Warfarin is the most effective anticoagulant at preventing thrombotic complications, but warfarin crosses the placenta and can cause miscarriage, spontaneous abortion, warfarin embopathy, or fetal intracranial hemorrhage.

Recommendation-Specific Supportive Text

1. The risk of catastrophic valve failure or stroke is prohibitively high for women with mechanical heart valves who cannot take dose-adjusted and frequently monitored anticoagulation throughout pregnancy.1–10

2. Much of the maternal morbidity and mortality during pregnancy occurs in women who are not receiving appropriate doses of anticoagulation because of improper administration, improper monitoring, or medication nonadherence. Women who are not able to receive therapeutic anticoagulation or do not have access to frequent monitoring and dose adjustment are at prohibitive risk for pregnancy.13–15

3. No anticoagulation strategy is optimally safe for both the mother and the fetus. Warfarin is safest for the mother but crosses the placenta and can cause fetal intracranial hemorrhage; fetal loss; and teratogenicity, particularly at doses >5 mg/d and when given during the first trimester, keeping in mind that the warfarin dose needed to maintain a therapeutic INR may change during pregnancy. Neither UFH nor LMWH crosses the placenta, but each is associated with higher rates of maternal complications than are seen with warfarin.3,4,6,16,18,20,23,25,35,36 Depending on a woman’s values and priorities, she may choose an anticoagulation strategy that minimizes maternal risk, minimizes fetal risk, or attempts to achieve a balance between maternal and fetal risk. Physicians should not assume a woman’s values or preferences, nor should physicians supplant their own preferences for those of the patient. Counseling and shared decision-making allows for a woman and her physician to choose the best anticoagulation to achieve the woman’s goals.

4. Warfarin crosses the placental barrier and results in anticoagulation of the fetus, as well as the mother. There is a higher risk of fetal intracranial hemorrhage if the mother is fully anticoagulated with warfarin during vaginal delivery. Women taking warfarin can minimize the risk...
Figure 18. Anticoagulation for prosthetic mechanical heart valves in women during pregnancy.

Colors correspond to Table 2. *Dose-adjusted LMWH should be given at least 2 times per day, with close monitoring of anti-Xa levels. Target to Xa level of 0.8 to 1.2 U/mL, 4 to 6 hours after dose. Trough levels may aid in maintaining patient in therapeutic range. Continuous UFH should be adjusted to aPTT 2 times control. aPTT indicates activated partial thromboplastin time; IV, intravenous; LMWH, low-molecular-weight heparin; UFH, unfractionated heparin; and VKA, vitamin K antagonist.
by switching to a heparin preparation before planned delivery.\textsuperscript{5,8,13,17–20}

5. Although LMWH does not result in an anticoagulated fetus, the risk of maternal hemorrhage is high if delivery occurs while the mother is on LMWH. Therefore, it is recommended that the mother be hospitalized before planned delivery, with discontinuation of long-acting anticoagulation and initiation of intravenous continuous infusion of UFH to keep aPTT >2 times control levels.\textsuperscript{19,20}

6. Intravenous heparin should be stopped long enough before delivery to reduce risk of maternal bleeding and allow safe placement of epidural anesthesia (typically at least 6 hours). Exact timing should be coordinated with the obstetrics and anesthesia teams.\textsuperscript{19,20}

7. Because warfarin results in an anticoagulated fetus, there is a high risk of fetal intracranial hemorrhage if vaginal delivery is attempted in a woman who is anticoagulated with warfarin. If a woman goes into labor while on warfarin, appropriate reversal of anticoagulation followed by cesarean section reduces the risk of fetal intracranial hemorrhage.\textsuperscript{3,22,23}

8. The teratogenic effects of warfarin are dose dependent. The rate of warfarin embryopathy is reduced (<3%) but not eliminated if the daily dose of warfarin is ≤5 mg/d.\textsuperscript{3,6,16,23,25,36,37} In most women, the effective dose of warfarin typically does not vary significantly during pregnancy.\textsuperscript{38} For women who require a dose ≤5 mg/d, continuation of low-dose warfarin throughout pregnancy poses the lowest combined risk to mother and fetus.\textsuperscript{3,6,16} The number of reported pregnancies on low-dose warfarin is relatively small, and not all publications have found improved fetal outcomes on low-dose warfarin,\textsuperscript{11} so caution should be exercised until more data are available.

9. If warfarin is taken in doses >5 mg/d during the first trimester of pregnancy, there is a >30% risk of fetal loss or embryopathy. For women who require >5 mg/d to maintain a therapeutic INR, replacing warfarin with dose-adjusted LMWH during the first trimester reduces fetal loss.\textsuperscript{3,6,10,15,16,23,39,40} While the patient is taking LMWH, anti-Xa levels should be monitored at least weekly and the dose adjusted accordingly. Fixed dosing is never appropriate, because it is associated with high maternal morbidity and mortality.\textsuperscript{41} After the first trimester, the fetal toxicity of warfarin is substantially lower, so switching back to warfarin for the second and third trimesters results in a reasonable balance between maternal safety and fetal safety.

10. In regions where LMWH is unavailable or cost-prohibitive, or if anti-Xa levels cannot be monitored, continuous infusion of UFH can be used as an alternative to LMWH during the first trimester for women who require a warfarin dose of >5 mg/d.\textsuperscript{37} If UFH is used during the first trimester, the dose should be adjusted to maintain an aPTT 2 times control. There are several disadvantages to UFH compared with LMWH: Women are at greater risk for line infections, osteoporosis, and heparin-induced thrombocytopenia, so UFH should be reserved for situations where dose-adjusted LMWH is not feasible.\textsuperscript{10} Intermittent subcutaneous injection of UFH is not an acceptable alternative because it is associated with prohibitive rates of valve thrombosis.\textsuperscript{42} UFH is associated with very high rates of valve thrombosis, stroke, and death in pregnant women with mechanical heart valves during the second and third trimesters.\textsuperscript{3,4,43}

11. In carefully selected women with thrombosis of a mechanical heart valve during pregnancy, low-dose, slow-infusion, tissue-type plasminogen activator (tPA) can be an alternative to surgical valve replacement. Women who are optimal candidates are hemodynamically stable and have obstructive prosthetic valve thrombosis, valve thrombosis with embolic complications, or nonobstructive valve thrombosis with a thrombus >10 mm.\textsuperscript{44} Given the high rates of fetal loss with cardiac surgery during pregnancy, thrombolysis is an attractive alternative for appropriately selected, hemodynamically stable women with mechanical valve thrombosis.

12. Although the teratogenicity of warfarin is highest during the first trimester, there is still a risk of pregnancy loss or fetal hemorrhage when warfarin is taken during the second and third trimesters. Therefore, after appropriate counseling, some women may choose to avoid warfarin entirely throughout pregnancy. For these women, dose-adjusted LMWH throughout pregnancy is the safest alternative. LMWH throughout pregnancy is associated with a higher rate of thrombotic complications than warfarin. However, many of the thrombotic events occur when LMWH is administered improperly or monitored erratically or if patients are nonadherent.\textsuperscript{8,14,15,39} When administered and monitored meticulously, LMWH can be safe.\textsuperscript{12} Effective dose monitoring includes weekly measurements of anti-factor Xa levels, with additional monitoring after dose adjustment.\textsuperscript{13} Measurement of trough levels to maintain a trough Xa level >0.6 IU/mL may help women maintain therapeutic anticoagulation while on LMWH.\textsuperscript{12,13}

13. When warfarin is taken at a dose ≤5 mg/d, the risk of warfarin embryopathy is reduced but not entirely eliminated. Some women, after discussion with their physicians, may choose to substitute
LMWH for low-dose warfarin during the first trimester to eliminate the risk of warfarin embryopathy. This choice improves fetal outcomes but at the cost of increased maternal thrombotic complications.1–3,12

14. Low-dose aspirin is regarded as safe during pregnancy and can be continued in women with mechanical heart valves if needed for other indications. There may be noncardiac indications for aspirin in pregnant women, such as prevention of preeclampsia.28

15. Studies using subcutaneous LMWH at a fixed dose without monitoring of anti-Xa levels in pregnant patients with mechanical prostheses found a high risk of valve thrombosis and maternal death. In pregnant women treated with dose-adjusted LMWH, the dose of LMWH required to maintain an adequate anti-Xa level 4 to 6 hours after administration increases throughout pregnancy.9,15,39,41

16. A randomized clinical trial of dabigatran in nonpregnant patients with mechanical heart valves showed an increased rate of thromboembolic and bleeding complications with dabigatran compared with warfarin.45 The safety and effectiveness of anti-Xa direct oral anticoagulants has not been established in patients with mechanical heart valves. Additionally, the safety of anti-Xa direct oral anticoagulants in pregnancy is unknown.30–32

17. Anti-Xa direct oral anticoagulants have not been shown to be safe in patients with mechanical heart valves, so they should not be used in pregnancy.

14. SURGICAL CONSIDERATIONS

Concomitant surgical procedures may be appropriate at the time of intervention for VHD in the interest of reducing periprocedural risk (eg, treatment of significant CAD) or for optimizing long-term outcomes (eg, adding a maze procedure for AF treatment). Consideration may also be given to treating moderate disease in the interest of obviating the need for subsequent reoperation—for example, treating aortic dilation in the presence of a BAV. This is particularly true when one can anticipate particular difficulty in the conduct of a subsequent reoperation, as may be the case for mitral valve intervention after AVR or in a patient with prior mediastinal irradiation for whom postoperative adhesions are often severe. The benefits of such concomitant procedures must be balanced against the potential impact on periprocedural risk due to added complexity. In particular, interventions that add significantly to aortic crossclamp time may be discouraged in patients with poor LV function or significant pulmonary hypertension. Prolongation of cardiopulmonary bypass time may increase renal injury, particularly among those with preexisting renal dysfunction. More complex procedures may also pose a particular risk in patients with fragile tissue integrity or general frailty, and the additional dissection that may be required in a reoperative setting may tip the balance away from imposing additional risk by performing concomitant procedures.

14.1. Evaluation and Management of CAD in Patients With VHD

14.1.1. Management of CAD in Patients Undergoing TAVI

Synopsis

CAD is common among patients presenting with AS, particularly the elderly. In the surgical experience, concomitant revascularization impacts long-term survival in a favorable way and is commonplace, as is preoperative coronary imaging. Similarly, there is an argument to be made for coronary revascularization among patients undergoing TAVI, although the effects on late outcomes are less well defined and may not be the same as for SAVR, given the different demographics and comorbidities of the TAVI versus SAVR populations. Nonetheless, at this point, diagnostic imaging and consideration of revascularization are appropriate (Figure 19).

Recommendation-Specific Supportive Text

1. The prevalence of CAD in patients with severe AS ranges between 15% and 80%,5 and varies depending on the definition of CAD used and the populations examined.6 The impact of CAD on outcomes is controversial,7,8 although one report
singed out severe CAD (defined by a SYNTAX score >22) and incomplete revascularization as the only independent predictors of death after TAVI.9 Assessment of the coronary anatomy is important in patients with severe AS to rule out obstructive CAD. Invasive coronary angiography is commonly performed. In patients with a low pretest probability of CAD, contrast-enhanced coronary CT angiography10 has an excellent negative predictive value.11,12 In patients with normal renal function, an option is to combine contrast-enhanced coronary CT angiography with CT assessment of the peripheral circulation and heart structure as an initial imaging test, reserving coronary angiography for the event that the contrast-enhanced coronary CT angiography is nondiagnostic or significant CAD is found. Invasive functional assessment of coronary lesions in TAVI candidates by using fractional flow reserve or instantaneous wave-free ratio is safe and feasible.13–15 Instantaneous wave-free ratio may be particularly attractive because it does not require the administration of a vasodilator and is less influenced by the effect of the stenotic aortic valve, although randomized clinical trials validating the utility of both are ongoing.

2. There are no RCTs to inform clinical practice on the benefits and timing of PCI in patients undergoing TAVI. The decision to perform PCI is therefore driven by myriad clinical factors (eg, presence of angina or ischemia, ability to take dual-antiplatelet therapy before TAVI) and anatomic factors (eg, lesion location and complexity, technical feasibility) and should be individualized. Overall, nonrandomized studies suggest that PCI before TAVI is safe and feasible,1 even in patients with left main disease.2 Conceptually, pre-TAVI PCI also allows a safer procedure and circumvents future post-TAVI PCI, which can be occasionally challenging. Staged PCI before TAVI is a common strategy in clinical practice and is associated with lower contrast volume and renal failure than is the strategy of TAVI with concomitant PCI,1 although the timing of pre-TAVI PCI remains controversial.

3. Multiple RCTs have been conducted to define the optimal management of CAD in patients without VHD based on the SYNTAX score to define
those least amenable to percutaneous treatment. Subsets of patients shown to have superior freedom from major adverse cardiac events include those with complex left main disease and those with a SYNTAX score $>33$. Accordingly, a surgical approach is reasonable in this subset of patients. Among SAVR patients, revascularization for those with significant CAD (>50% stenosis) has been shown to impact late risk of mortality favorably.\(^4\)

### Synopsis

Coronary imaging in the setting of VHD defines anatomy that may be at risk during surgery or intervention. Given their similar demographic profiles, CAD and VHD frequently coexist, and in the case of secondary MR they have a pathophysiological link. Revascularization, in turn, can impact periprocedural risk or long-term outcome. In the case of secondary MR, revascularization may positively impact the valve disease via reverse remodeling of the LV. In the surgical setting, where repeat intervention is at high cost to the patient, efforts are typically made to correct all surgically correctable disease present at the index operation. Accordingly, an aggressive approach to revascularization is appropriate. In the setting of percutaneous interventions, however, the option of sequential interventions with interval tests of improvement may be appropriate. In either case, less invasive imaging via contrast-enhanced coronary CT angiography is increasingly adopted.

### Recommendation-Specific Supportive Text

1. CAD is frequently present among patients with VHD\(^1\)^\(^4\) and may contribute to angina pectoris among those with aortic valve disease.\(^3\)^\(^4\) Knowledge of coronary anatomy contributes to risk stratification, in addition to directing concomitant coronary revascularization. There is a very low prevalence of CAD among men $<40$ years of age and premenopausal women with no atherosclerotic risk factors\(^2\)^\(^5\)^\(^7\) or history of mediastinal radiation.\(^8\)

2. Functional MR occurs in patients with structurally normal valve leaflets and chordae because of LV dysfunction, including regional wall motion abnormalities or global dilation with displacement of the papillary muscles, leaflet tethering, annular dilation, and decreased closing forces from reduced contractility.\(^9\)^\(^10\) Because this LV dysfunction may be attributable to CAD and accompanying myocardial ischemia, the assessment of coronary anatomy status is necessary to complete the diagnosis and allow evaluation of revascularization options.

3. Contrast-enhanced coronary CT angiography is an alternative to coronary angiography among selected patients who are at low to intermediate pretest probability of CAD before valve surgery.\(^12\) This does not include patients who have active symptoms of angina, those with documented ischemia, or those with a prior history of CAD, all of whom should have selective coronary angiography. Recent studies, most often in the setting of a pre-TAVI evaluation, have demonstrated diagnostic sensitivity of $>90\%$, specificity of $60\%$ to $90\%$,\(^13\)^\(^15\)^\(^21\) and accuracy of $>90\%$.\(^21\) Contrast-enhanced coronary CT angiography may be safer than coronary angiography in selected patient populations, such as those with IE and vegetations on the aortic valve. However, a positive contrast-enhanced coronary CT angiogram, defined as the presence of epicardial CAD, requires confirmation with invasive coronary angiography to establish the need for and extent of CABG. The risk of radiation exposure and renal failure because of the contrast injection should be taken into consideration.

4. The presence of uncorrected CAD has been shown to negatively impact both perioperative\(^22\)^\(^23\) and late outcomes of surgery for VHD.\(^16\) Accordingly, concomitant CABG has been favored. These studies of concomitant CABG at the time of valve surgery have demonstrated little or no adverse impact on the acute perioperative mortality rate, despite increased cross-clamp and cardiopulmonary bypass times. Moreover, combined CABG
and valve surgery reduces the rate of perioperative myocardial infarction, and incomplete revascularization is associated with greater postoperative LV systolic dysfunction and a reduced survival rate after surgery as compared with patients who receive complete revascularization. For more than a decade, improved myocardial preservation techniques have been associated with reduced overall operative mortality rates, and it has become standard practice to bypass all significant coronary artery stenoses, when possible, in patients undergoing valve surgery. In patients with a significant stenosis of the left anterior descending artery, a left internal thoracic artery graft should be used if possible. Hybrid PCI followed by surgical valve repair or replacement has been reported favorably but is restricted to patients at high risk with a combined surgical approach.20

### 14.2. Intervention for AF in Patients With VHD

**Recommendation-Specific Supportive Text**

1. Surgical ablations, including pulmonary vein isolation and atrial maze at the time of valvular surgery and other open cardiac operations, have been demonstrated in multiple studies to reduce the recurrence of AF.14–16 Various approaches to pulmonary vein isolation and modified left atrial, right atrial, and bi-atrial maze procedures entail longer procedure times, with higher risks of operative complications and permanent pacemaker implantation.1–4 These adverse outcomes, coupled with the lack of large randomized trial data confirming mortality and stroke benefit, should be examined with the patient.

2. The atrial maze procedure properly refers to a specific bi-atrial lesion set performed by a “cut-and-sew” technique or with tissue ablation technologies, including cryoenergy or radiofrequency. Of note, the term “maze” is often loosely applied to many variations of the original lesion set that may be less effective. When performed with complete encirclement of the pulmonary veins, most commonly in combination with mitral valve repair or replacement but also with aortic or tricuspid valve procedures, the maze procedure affords freedom from AF with an efficacy similar to that of catheter-based approaches.1,2,12–15 Patients undergoing combined atrial maze procedure at the time of operation for MR have a greater freedom from recurrent AF than those who did not have a maze procedure.11 In patients with recurrent AF who are to undergo surgical correction of MR, catheter ablation is best deferred in favor of a concomitant surgical maze, thereby avoiding the potential complications of a catheter maze and a second procedure for the patient.

3. A reduction in thromboembolism has been demonstrated by LA ligation/excision, although the benefit is less evident in those patients who maintain anticoagulation.16–19 Discontinuation of oral anticoagulation has also been associated with late stroke, highlighting that the LA appendage is not the exclusive source of all thrombi in patients with AF. Therefore, there are insufficient data to support routine discontinuation of anticoagulation in patients with AF who are undergoing LA ligation/excision.

4. Ablation with radiofrequency/cryoenergy or atrial suture lines provides an endocardial thromboembolic milieu, and in addition, surgical LA appendage occlusion can be incomplete.20–22 In the context of atrial arrhythmias, manipulation of the LA, and post-cardioversion/defibrillation stunning, atrial mechanical function can be slow to recover. The resultant stasis and thrombogenic endocardial lesions provide a nidus for thrombus development, placing this group of patients at

<td>5. For patients without atrial arrhythmias who are undergoing valvular surgery, LA appendage occlusion/exclusion/amputation is potentially harmful.21</td>
</tr>
</tbody>
</table>

**Synopsis**

For patients undergoing valve surgery with symptomatic AF or atrial flutter, concomitant maze procedure with or without atrial appendage occlusion/exclusion/amputation is a proven treatment for the atrial arrhythmia but requires postoperative anticoagulation for at least 3 months after the procedure (Figure 20).
risk of stroke. Nonrandomized registry data indicate that stroke in the first 3 months after catheter ablation is driven chiefly by discontinuation of oral anticoagulation. Both US and European guideline statements on catheter ablation recommend (on the basis of expert opinion alone) anticoagulation during this periprocedural phase while the endocardium heals from the ablation. By analogy, patients who have had surgical ablation should be managed with at least 3 months of anticoagulation, regardless of their CHA2DS2-VASc risk score. Subsequent anticoagulation should be based on evaluation of arrhythmia recurrence in the context of their CHA2DS2-VASc score. Anticoagulation should also be given for at least 3 months after LA ligation/excision. For patients receiving bioprostheses, a VKA would be the preferred method of anticoagulation for the first 3 months (see Section 2.4.3).

5. A higher incidence of early AF in all patients after LA appendage occlusion/exclusion has been demonstrated. Together with the recognition that most patients do not develop AF after surgery, preemptive LA appendage occlusion in patients without preexisting AF cannot be recommended. No stroke benefit has been observed in this group of patients with no preemptive history of AF.

15. NONCARDIAC SURGERY IN PATIENTS WITH VHD

15.1. Diagnosis of Patients With VHD Undergoing Noncardiac Surgery

**Synopsis**

The evaluation of patients with VHD who are undergoing noncardiac surgery is dependent on the type and
Recommendation-Specific Supportive Text

1. After a careful clinical evaluation and preoperative resting 12-lead ECG, patients being evaluated for noncardiac surgery who have known or suspected VHD of moderate or greater degree benefit from TTE.5 If there has been no change in clinical course, an echocardiogram within the past 12 months can be used. Most adverse events have occurred because the diagnosis of VHD was not known to the surgical team. The echocardiographic evaluation should quantify the severity of valve stenosis or regurgitation, calculate systolic function, estimate diastolic function, evaluate LV size and myocardial structure, estimate RV size and function, and estimate pulmonary artery systolic pressure.4 AS is present in 1% to 2% of all patients >65 years of age and 3% to 8% of all patients >75 years of age. Severe AS is associated with an increased risk during noncardiac surgery, depending on the specific degree of valve narrowing, LV systolic function, concurrent CAD, type of surgery, and other risk factors associated with surgery. Rheumatic MS may also be poorly tolerated during the altered hemodynamics of anesthesia and noncardiac surgery. Left-sided regurgitant lesions are better tolerated but still convey increased risk, particularly if the anesthesiologist and surgeon are unaware of the diagnosis or severity of valve disease.

15.2. Management of the Symptomatic Patient

| Recommendation for Management of the Symptomatic Patient With VHD Undergoing Noncardiac Surgery |
|-------------------------------------------------|-------------------------------------------------|-------------------------------------------------|
| COR | LOE | Recommendation |
| 1   | C-EO | 1. In patients who meet standard indications for intervention for VHD (replacement and repair) on the basis of symptoms and disease severity, intervention should be performed before elective noncardiac surgery to reduce perioperative risk if possible, depending on the urgency and risk of the noncardiac procedure.1 |

Synopsis

Symptomatic patients with severe VHD benefit from valve intervention before noncardiac surgery, if possible.

Recommendation-Specific Supportive Text

1. Noncardiac surgery patients with symptomatic severe AS have the highest risk of cardiac complications; the estimated rate of cardiac complications in patients with undiagnosed severe AS undergoing noncardiac surgery is 10% to 30%. AVR (SAVR, TAVI) performed before elective elevated-risk noncardiac surgery in symptomatic patients with severe AS will prevent hemodynamic instability during, as well as after, noncardiac surgery.1–7 In AS patients who are undergoing noncardiac surgery, there is lack of data on the efficacy or safety of TAVI,8 but TAVI is a reasonable option to avoid delay of semi-urgent noncardiac surgery. In hemodynamically unstable patients at high to prohibitive surgical risk for AVR, balloon aortic valvuloplasty as a bridging strategy may be an option.9–11 Symptomatic patients with rheumatic MS (the pathophysiology and implications of rheumatic MS and AS are similar) or patients with pulmonary artery systolic pressure >50 mmHg benefit from valvular intervention before elective noncardiac surgery according to recommendations for rheumatic MS. Left-sided regurgitant lesions also convey increased cardiac risk during noncardiac surgery.1,2 Although these lesions are generally better tolerated than stenotic valvular disease, in patients with MR and AR who are undergoing elective elevated-risk (ie, intermediate- or high-risk) noncardiac surgery and who meet standard indications for intervention, mitral or aortic valve surgery (repair or replacement) optimally should be performed before noncardiac surgery.
15.3. Management of the Asymptomatic Patient

### Recommendations for Management of the Asymptomatic Patient With VHD Undergoing Noncardiac Surgery

### Synopsis

In asymptomatic patients with significant VHD who do not meet standard criteria for intervention, the risk associated with the noncardiac procedure can be minimized by choosing an anesthetic approach that is appropriate to the valve lesion and ensuring a higher level of intraoperative (and perioperative) monitoring, taking into account the underlying valvular abnormality, its effect on LV function, and comorbidities. In patients with VHD, the cardiovascular risk of noncardiac surgery is also impacted by other cardiovascular conditions, such as LV and RV dysfunction, CAD, pulmonary hypertension, and peripheral artery disease. In patients with moderate or greater degrees of AS, the hemodynamic effects of anesthesia and surgery are poorly tolerated; predictors of adverse outcomes include severity of AS, coexisting MR, pulmonary hypertension, and CAD. However, these comorbidities also increase the risk of AVR. Data are limited, but the risk–benefit ratio continues to favor managing asymptomatic patients with severe AS who are undergoing noncardiac surgery with hemodynamic monitoring and optimization of loading conditions, rather than considering prophylactic AVR. The patient with rheumatic MS who is undergoing noncardiac surgery is treated in a manner similar to the patient with AS. Regurgitant lesions also convey an increased risk of cardiac complications in patients undergoing noncardiac surgery and thus require careful evaluation and hemodynamic monitoring.

### Recommendation-Specific Supportive Text

1. Asymptomatic patients with severe AS and a normal LVEF can undergo noncardiac surgery with acceptable risk, particularly in the absence of severe CAD.1-3 Thus, pre-operative evaluation to exclude severe CAD with CT or angiographic imaging may be useful. In these patients with severe asymptomatic AS, cardiac complications can be reduced by periprocedural continuous optimization of loading conditions, thereby avoiding hypotension and tachycardia. Sinus rhythm with normal heart rate should be maintained. Tachycardia and systemic hypotension may result in decreased coronary perfusion pressure, development of arrhythmias or ischemia, myocardial injury, cardiac failure, or death. Periprocedural hemodynamic monitoring with a right-heart catheter or intraoperative TEE may be particularly useful to allow continuous optimization of loading conditions. Intraoperative and postoperative monitoring of blood pressure and intracardiac volume are implemented starting in the preoperative period and continuing until hemodynamics are stable, up to 24 to 48 hours after the procedure. General anesthetics are well tolerated, and the anesthetic agents should be chosen to maintain sinus rhythm and normotension. Phenylephrine or norepinephrine can be used to increase blood pressure in patients with no significant CAD.9,10 In case of systemic hypertension, arterial dilators, such as short-acting calcium channel blockers, are preferred. Epidural or spinal anesthetic interventions should be modified to avoid rapid changes in systemic pressure, using only high-dilution neuraxial local anesthetic agents in combination with opioids.11-14

2. In asymptomatic patients with moderate or greater degrees of rheumatic MS with a pulmonary artery systolic pressure <50 mmHg, elevated-risk noncardiac surgery can be performed with invasive hemodynamic monitoring to optimize loading conditions. Maintenance of LV preload and sinus rhythm should be the targets in the perioperative period. Preload should be maintained at a level high enough to allow an adequate forward cardiac output across the stenotic mitral valve but low enough to avoid pulmonary edema. Preload attainment can be challenging and requires measurement of cardiac output and pulmonary wedge pressure. Of particular concern is judicious intravenous fluid administration, so as to avoid increases in the LA pressure and pulmonary capillary pressure that may precipitate
acute pulmonary edema. Tachycardia should be avoided because of the shortened diastolic LV filling time across the stenotic mitral valve, resulting in an increase in LA pressure. In asymptomatic patients with significant rheumatic MS and with a pulmonary artery systolic pressure >50 mm Hg, the risk of elective intermediate- to high-risk noncardiac surgery is considerably higher, so these patients should be evaluated and treated as outlined in the rheumatic MS section (Section 6.2).

3. In asymptomatic patients with significant MR and normal LV systolic function with a pulmonary artery systolic pressure <50 mm Hg who are undergoing elective noncardiac surgery, the overall hemodynamic goals are avoidance of both increased afterload and bradycardia by choosing the appropriate anesthetic scheme. Left-sided regurgitant lesions convey chronic LV volume overload and increased cardiac risk during noncardiac surgery but are better tolerated than is stenotic valvular disease. Patients with significant MR undergoing noncardiac surgery had higher rates of postoperative HF and myocardial infarction than did controls without MR. The combination of neuraxial local anesthetics and opioids produces a favorable systemic vasodilation for patients with regurgitant valve lesions. Patients with regurgitant lesions will also do well with general anesthesia, which also lowers systemic vascular resistance. However, preload should be maintained. Invasive hemodynamic and/or intraoperative TEE monitoring allows for continuous optimization of LV filling pressures and LV function during and after the operative procedure. Patients should be admitted to an intensive monitoring setting for up to 24 to 72 hours after the procedure. In functional MR, especially in these patients for whom very careful attention to afterload control and fluid balance is crucial, anesthetic considerations should also include management of the underlying heart disease (ie, ischemic heart disease, hypertrophic cardiomyopathy).

4. Patients with severe AR are prone to hemodynamic instability because of the detrimental effects of increased volume on myocardial wall stress. The perioperative stress associated with noncardiac surgery may lead to hypotension, arrhythmias, HF, or even death. Patients with significant AR undergoing noncardiac surgery had a higher in-hospital mortality rate and higher morbidity rate, including postoperative myocardial infarction, stroke, pulmonary edema, intubation >24 hours, and major arrhythmias, than those of case-matched controls without AR. Decreased LV systolic function, elevated serum creatinine >2 mg/dL, and intermediate- to high-risk noncardiac surgery were predictors of higher risk of cardiopulmonary complications and death.

Avoid bradycardia when AR is present because of the increase in total diastolic time. These patients are monitored with invasive systemic arterial and venous catheters and/or TEE and are admitted postoperatively to an intensive monitoring setting.

16. EVIDENCE GAPS AND FUTURE DIRECTIONS

Many recommendations for the evaluation and management of VHD continue to be based on clinical experience and observational studies, with prospective RCTs limited mostly to new devices. We recommend that research on valve disease span the spectrum from basic science to prospective randomized trials, including medical therapy, and that studies focus on each stage of the disease process, from the patient at risk to the patient with end-stage disease. Newer approaches, such as artificial intelligence and machine learning, as well as imaging and engineering advances, may provide sophisticated tools for diagnosis and therapeutics. Research should be patient centered, with patients included at every stage of the research process to ensure that questions and outcomes important to patients are included in the study design, implementation, and reporting.

16.1. Prevention of Valve Disease: Stage A

On a worldwide basis, rheumatic fever remains the primary cause of VHD; global health systems outcomes studies are needed to identify impediments to successful primary and secondary prevention of rheumatic heart disease. Other approaches to prevention, such as vaccine development, and delaying disease progression once valve damage is present should also be explored. Disease prevention in patients at risk of other types of valve disease is needed, including the control of known cardiovascular risk factors. Some subgroups at risk of calcific AS can be identified, such as those with a congenital BAV or elevated lipoprotein(a) levels. However, there are no known therapies to prevent valve dysfunction in these patients. Basic science studies on the genetic and pathobiological causes of valve dysfunction will provide insight into mechanisms of disease that might allow identification of patients at risk and allow early intervention to prevent disease initiation.
16.2. Medical Therapy to Treat or Prevent Disease Progression: Stage B

In patients with early VHD, including those with calcific or myxomatous disease, there are currently no therapies to prevent disease progression in the valve leaflets. Instead, current recommendations are directed toward patient monitoring, with the intent to intervene once severe disease is present that results in symptoms or abnormal cardiovascular function. Basic science studies are needed to identify potential targets for prevention of progressive VHD. Focused translational studies using sensitive, advanced imaging markers of disease progression may allow more rapid clinical implementation and better design of RCTs for promising new therapies. There also has been little consideration of the interaction of valvular, ventricular, and vascular involvement in the disease process. Additional studies are needed on therapies that might prevent the adverse consequences of VHD, such as LV dysfunction and pulmonary hypertension. Most importantly, patient education and empowering patients to be active participants in managing their health conditions and participating in shared decision-making are essential.1-5

16.3. Optimal Timing of Intervention: Stage C

Current approaches to identifying the optimal timing of intervention in patients with progressive valve disease are suboptimal. Symptom onset is a subjective measure and may occur too late in the disease course for optimal long-term outcomes. Despite the availability of sophisticated approaches for measurement of LV volumes, systolic function, diastolic function, and other measures of myocardial performance, recommendations continue to rely on simple linear dimensions used in published series, with data that may not reflect contemporary clinical outcomes. Studies are urgently needed that evaluate the value of newer measures of LV size, function, and myocardial structure in predicting outcomes after valve intervention, especially in patients with chronic severe AR. However, LV enlargement and dysfunction are late consequences of valve dysfunction; as more durable approaches to restoring normal valve function are developed, the benefit–risk balance for intervention will shift to earlier in the disease. Studies examining the role of earlier markers of myocardial dysfunction, such as strain and strain-rate imaging, diastolic dysfunction, circulating blood markers, and other novel approaches to defining the optimal timing of intervention, also are needed.

Few studies have included adequate numbers of older adults to make specific recommendations for this group of patients, for whom particular concerns, such as cognitive function, frailty, and mobility challenges, may change the decision algorithms. In addition, women and minorities often are underrepresented in clinical trials. Directed efforts are needed to ensure all patient groups are included with numbers adequate to perform separate data analysis.

Given the relatively low risk associated with intervention in otherwise healthy patients and the improved options for valve repair or replacement, RCTs of intervention for severe asymptomatic VHD will be important and are in progress for some conditions, such as severe AS. Other specific conditions where clinical equipoise exists are asymptomatic severe AR with normal LV systolic function, severe primary MR with normal LV function and a high likelihood of valve repair, and the role of intervention for TR. Data from large, carefully designed registries are also needed for defining and improving quality of care. Long-term follow-up will be needed to ensure the lifetime risks of a prosthetic valve or valve repair are balanced against any benefits attributable to earlier intervention.1-4

16.4. Better Options for Intervention: Stage D

Better options are needed for valve repair and replacement. The timing of intervention is based on the balance between outcomes with native valve disease and the risk and long-term durability of the valve after intervention. As valve repair and replacement options improve, the balance will shift toward earlier intervention. A valve substitute is needed that can be safely and reliably implanted, is nonthrombogenic, has hemodynamics similar to a normal native valve, and is durable. Transcatheter valve procedures offer the promise of safe implantation and excellent hemodynamics, but long-term durability beyond 5 years is not yet known. In patients who require mechanical valve replacement, oral therapy is needed that provides effective anticoagulation with a low risk of complications and no negative impact on quality of life.

Moderate to severe VHD is present in 2.5% of the US population and increases in prevalence with age. The disease affects between 4% and 9% of those 65 to 75 years of age and 12% to 13% of those >75 years of age. Many of these patients require surgical or interventional procedures. However, even with intervention, overall survival is lower than expected, and the risk of adverse outcomes attributable to VHD is high, because of both limited options for restoring normal valve function and failure to intervene at the optimal time point in the disease course. Research is urgently needed on almost every aspect of VHD to ensure that patients who already have VHD receive optimal therapy and to prevent VHD in those at risk. Approaches to improving outcomes in patients with VHD include 1)
national and international registries and RCTs, 2) continuous evaluation of outcomes data at each Comprehensive and Primary Heart Valve Center, and 3) focus on patient-centric care, with involvement of the patient in the decision-making process (Table 26). More accessible quality and outcome data are also needed from Comprehensive Valve Centers to assist cardiologists and patients to make well-informed choices.1–3

Table 26. Evidence Gaps and Future Directions for Patients With VHD

<table>
<thead>
<tr>
<th>Evidence Gaps</th>
<th>Future Directions</th>
</tr>
</thead>
<tbody>
<tr>
<td>Medical therapy for progressive valve disease (Stage B)</td>
<td>Disease mechanisms: Basic science to identify specific targets to slow or reverse disease progression. Medical intervention: Targeted therapy using advanced imaging endpoints to study disease mechanisms. Ventricular and vascular interactions: Dynamic interplay between valve disease severity and changes in ventricular anatomy and function. Modulation of ventricular and vascular dysfunction in patients with VHD.</td>
</tr>
<tr>
<td>Optimal timing of intervention (Stage C)</td>
<td>Improved measures of disease severity: Validation of newer measures of LV size (eg, volumes instead of dimension) and function (eg, strain) for timing of intervention decisions. Evaluation of nonimaging parameters (serum markers and other novel approaches) for timing of intervention. Timing of intervention: Timing of intervention in asymptomatic patients with valve regurgitation. Intervention for asymptomatic severe AS. Intervention for moderate AS with LV dysfunction. Identification of patients with secondary MR who benefit from intervention. Patient-centered research: Involvement of patients in identifying research questions, study design, and definition of outcomes. Inclusion of diverse patient groups: Adequate representation of diverse patient populations in RCTs for VHD. Decision aids: Development and validation of improved decision aids for shared decision-making with patients.</td>
</tr>
</tbody>
</table>

AF indicates atrial fibrillation; AS, aortic stenosis; AVR, aortic valve replacement; LV, left ventricular; MR, mitral regurgitation; RCT, randomized controlled trial; SAVR, surgical aortic valve replacement; TAVI, transcatheter aortic valve implantation; VHD, valvular heart disease; and VKA, vitamin K antagonist.

(Continued)
This table represents the relationships of committee members with industry and other entities that were determined to be relevant to this document. These relationships were reviewed and updated in conjunction with all meetings and/or conference calls of the Writing Committee during the document development process. The table does not necessarily reflect relationships with industry at the time of publication. A person is deemed to have a significant interest in a business if the interest represents ownership of $\geq 5\%$ of the voting stock or share of the business entity, or ownership of $\geq $5000 of the fair market value of the business entity; or if funds received by the person from the business entity exceed 5\% of the person’s gross income for the previous year. Relationships that exist with no financial benefit are also included for the purpose of transparency. Relationships in this table are modest unless otherwise noted. Please refer to https://www.acc.org/guidelines/about-guidelines-and-clinical-documents/relationships-with-industry-policy for definitions of disclosure categories or additional information about the ACC/AHA Disclosure Policy for Writing Committees.

*Writing committee members are required to recuse themselves from voting on sections to which their specific relationships with industry and other entities may apply.
†Significant relationship.

</table>

This table represents all relationships of reviewers with industry and other entities that were reported at the time of peer review, including those not deemed to be relevant to this document, at the time this document was under review. The table does not necessarily reflect relationships with industry at the time of publication. A person is deemed to have a significant interest in a business if the interest represents ownership of ≥5% of the voting stock or share of the business entity, or ownership of ≥$5000 of the fair market value of the business entity; or if funds received by the person from the business entity exceed 5% of the person’s gross income for the previous year. Relationships that exist with no financial benefit are also included for the purpose of transparency. Relationships in this table are modest unless otherwise noted. Names are listed in alphabetical order within each category of review. Please refer to [https://www.acc.org/guidelines/about-guidelines-and-clinical-documents/relationships-with-industry-policy](https://www.acc.org/guidelines/about-guidelines-and-clinical-documents/relationships-with-industry-policy) for definitions of disclosure categories or additional information about the ACC/AHA Disclosure Policy for Writing Committees.

*Significant relationship.
†No financial benefit.

ACC indicates American College of Cardiology; AHA, American Heart Association; DSMB, Data and Safety Monitoring Board; NIH, National Institutes of Health; PCORI, Patient-Centered Outcomes Research Institute; and UT, University of Texas.
